Considering, first of all, the average of the first six experiments only, we see that 2·03 horse-power was transmitted with an expenditure of 6·21 horse-power at the shaft of the dynamometer, which corresponds to a return of ·327 horse-power. And this conclusion is abundantly corroborated on comparing the figures in the different columns. For a mean speed of 94·2 revolutions per minute at the dynamometer, the work of mechanical transmission, including the rotation of the generator when light, reached $·3 \times 94·2 = 28·26$ kilogrammetres, or ·377 horse-power, and the figure given above for the return is therefore raised to $2·01 : (6·21 - ·38) = ·345$; but I attach little importance to this correction, which is minimised by the impossibility of suppressing this supplementary work in ordinary cases, which would comprise at the least the mechanical resistance of the bearings of the generating machine. It is, however, more especially in the results obtained at different parts of the installation that I feel the greatest interest; these results are given in Table II. They are very easy of interpretation if I state the fact that each of the three parts of the installation gives a useful effect of about ·70. The resistances of the generator, the heat developed in it, the losses at the brushes and by sparking account for a loss of energy amounting to 30 per cent. Under the conditions of the experiment the heat developed in the circuit represented 30 per cent. of the electric energy put into it. Doubts might have been expressed as to whether some connection did not exist between the lead and return wires had not the wires been supported on posts throughout the whole distance, and it suffices to remark in this connection that the loss between the generator and the receiver was, on an average, equal to 122 kilogrammetres, which corresponds to 160 ohms, the total resistance of the circuit.

Finally, the resistances of the receiver, its brushes and sparking at its commutator also absorbed 30 per cent. of the electric work which was imparted to it. In round numbers, the useful effect differed about $·70^3 = ·343$.

In future it will be right to expect in all experiments of this nature measurements of the work which acts on each part of the transmitting apparatus. The means we possess for measuring electric energy are far ahead of those with which we can measure work or heat, and we would particularly call attention to the facility and certainty afforded by the use of currents in this connection.

Electrical units are now in perfect accord with mechanical units. In the *data* relating to the seventh experiment, which

Digitized by Google

may be placed side by side with the preceding ones, we have only the following readings :—

	H.-P.
Electric work of the generator	4·64
Intermediate loss by difference	1·34
Electric work at the receiver	3·30
Intermediate loss by difference	·31
Work actually transmitted	2·79
Effective return of the circuit	·711
Effective return of the receiver	·843

The latter figure differs greatly from those comprised in the general table; but we may conclude without much danger of mistake from the ·711 given above, that the effective work transmitted, favoured by a notable increase in speed, would not have differed greatly from those which were measured directly.

Beginning with the resistances of the two machines when at rest, we can calculate the work lost in heat, and subtract from this again the supplementary work lost either by friction, sparking, or by possible increase of the electrical resistance during working. It will be sufficient for us to say that the total losses in the generator amounted to ·92 h.-p., and in the receiver to ·36 h.-p. This difference is explained by the relative smallness of the work which is called into play in the receiver, and its measurement, whilst completing the figures already given as to the different losses, renders an account of all the practical conditions of the experiments. I cannot finish without bearing testimony to the care and skill with which Dr. Hopkinson made his calculations.

Summing up, it may be stated that the power actually transmitted to a distance of 8·5 kilometres (about 5·28 miles) over an ordinary telegraph wire of 4 millimetres diameter, according to M. Deprez's method of connecting up the machines, represents a third of the motive power. If the current remained the same, and the resistance of the circuit were taken away, the corresponding effective work would be raised, according to these figures, to nearly one-half the motive power.

The experiment, under rigid supervision at all points, established the fact of the transmission of 2 h.-p., and in one case 2·79 h.-p., to a considerable distance. The foregoing results were obtained with a speed at the generator of 590 revolutions per minute. A further series of experiments, in which the electrical measurements were made under the supervision of my fellow-worker, M. Cornu, established an average speed of 814 revolutions. An account of these will be given at the next meeting, but I may say here that an examination of the figures taken at the higher speed, when 3·68 h.-p. was transmitted, shows that the return, allowance being made for the power absorbed by mechanical transmission to the generator and by its shaft, was raised at 890 revolutions to 42 per cent. instead of of 35, and without this allowance to ·33 in place of ·32.

(TO BE CONTINUED.)

IMPROVEMENTS IN DISTRIBUTING AND MEASURING ELECTRICITY, &c.

The following has been thought of more importance than to be passed over in our usual short abstracts. It is an abstract of a patent taken out by Dr. Hopkinson, F.R.S., on the 27th July last. It is numbered 3576. The specification, as will be seen, deals (1) with distributing, (2) with measuring electricity. One aim of the inventor is to ascertain the potential at the far end of the circuit, and for this purpose he uses a differentially wound galvanometer. The more important idea, however, is to minimise the quantity of metal required for conductors by a special arrangement of the circuits:—

"Many devices have been proposed and used for keeping the difference of potential between the terminals of dynamo machines constant, or for indicating when such potential deviates from its standard amount. When the electricity is to be used at a distance from the dynamo, and conductors of a sensible resistance are used, it is proper to maintain constant the difference of potential at the end of such conductors where the electricity is used and not at the dynamo itself. If E be the difference of potential of the poles of the dynamo, R the resistance of the conductors from the dynamo to the place where the electricity is to be used, and C the current, it is necessary to maintain not E constant but E − C R, which is equal to the difference of potential of the two conductors at their other end. This is attained by using a differential regulating or indicating apparatus, as shown diagrammatically in Fig. 1. A is the dynamo machine, with lamps all placed near each other, connecting the conductors, but remote from A. The indicating apparatus is wound with a coil of thin wire making many convolutions. This coil is connected to the poles of the dynamo electric machine at E and F, and is, therefore, a shunt to the circuit. The indicating apparatus is also wound with a thick coil through which the whole current may pass, or a proportional part thereof, from G to H, the direction of the current in the thick coil being opposite to that in the thin coil, as indicated by the arrows. It is preferred to use a proportional part of the current through the thick coil, as it is then easy (by properly adjusting the resistance) to secure that, for the particular value of R which occurs, E − C R shall be constant. It is best to make the thin coil of German silver as it is important that its resistance shall not vary

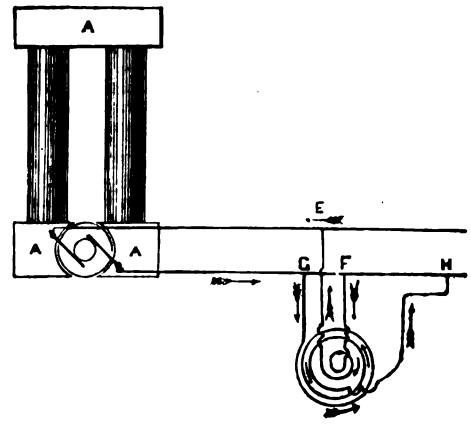

FIG. 1.—Diagram of Differential Regulating Apparatus.

sensibly. Fig. 2 shows how the differential instrument may be arranged to act as a relay. A B are the coils of thick wire, and C D the coils of thin wire, both wound on the same cores, the preponderating effect of the thin wire being opposed by the spring E attached to the movable armature G, carrying the contact piece F, which makes contact with H or I, according as E − C R is too great or too small, and so closes the circuit of one or other of two electric bells, or of other apparatus for indicating or regulating. The application of this instrument to an extended system of electrical supply with a network of distributing mains is important. For each machine a pair of feeders are provided, of a size appropriate to the current they are to carry, but independent of the distance they have to go. Each pair of feeders goes to, and is connected to, some part or other of the system of distributing mains, and by the use of this invention the difference

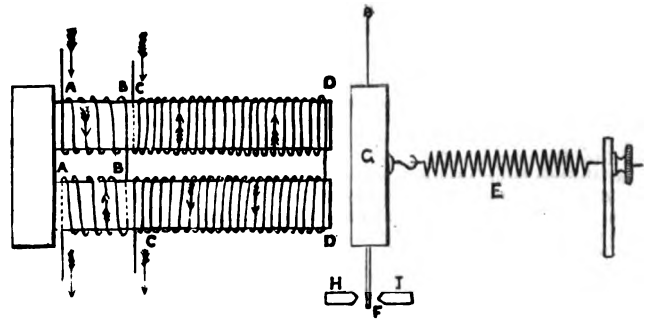

FIG. 2.—Showing how the Differential Arrangement illustrated in Fig. 1 may be made to act as a Relay.

of potential is kept constant at or near the point where the feeders join the distributing mains."

We shall give that portion of the patent dealing with Dr. Hopkinson's method of combining a comparatively high potential in the conductors with a low potential in the houses of a circuit, and also his measuring apparatus, in our next issue.

ELECTRIC LIGHTING AND THE BOARD OF TRADE

The following letter from Mr. Arnold White, secretary of the Edison Electric Light Company, appeared in *The Times* of March 24:—

"Sir: The draft Provisional Order issued by the Board of Trade bears evidence of a strong desire to facilitate the introduction of electricity into streets and houses for general purposes. At the same time, there are certain essential points for which no provision is made, and restrictions imposed which, in the opinion of the electric lighting companies, must inevitably act contrary to the intentions of the framers of the Act.

"This being entitled an Act to facilitate electric lighting, &c., it is assumed that anything which seriously hampers or prevents the spread of this method of illumination will, unless good reason is shown to the contrary, receive effective consideration by the Government and by the department. When Mr. Chamberlain was settling the amendments to the Bill introduced in the House of Lords it was resolved—first, that the electric companies should not prescribe their own or any form of lamp; and, secondly, that the charge to the consumer should be, not for light or for work done, but for electricity. Now, electricity used in a commercial sense is almost a metaphysical term. It cannot be stored, delivered, or measured except in the act of performing work. This being so, it would seem the natural course for the electric companies to base their charges not on the number of ampere hours registered by the meters, which the public do not understand, but on the light supplied or the power used by customers, which provides a unit that the public do understand. But there is a stronger reason for this method of charge in the interests of the public, of the local authorities, and of the electric companies. The Act as it stands is an Act for the perpetuation of bad lamps, and consequent obstruction to economical improvements. At the present time the most economical lamp known requires about ·75 of an ampere of electricity to produce 16 candles of light for a period of one hour.

Digitized by Google

To-morrow a lamp might well be invented which will produce the same amount of light with a consumption of half the quantity of electricity. Under the Act there is no incentive given to the companies or to inventors to supply a more economical lamp, because the only effect of so doing would be that the amount of electricity sold would be less with the better and more economical lamp than is the case with the obsolete and more wasteful lamp. This is a blot so great, that unless the methods of charge are revised in such a way as to promote the use of good and economical lamps, the progress of electric lighting will be inevitably hindered in this country. This is as if in the early history of the gas enterprise artificial restrictions were imposed on the invention of more economical methods of consumption.

"In the determination to act in a fair spirit, Mr. Chamberlain resolved that the companies should not prescribe what lamp should be used within the areas supplied by them. Now, a lamp is as much a part of an electric system as the dynamos or the conductors. In fact, the lamp, the dynamo, and the conductors must be correlative, otherwise both economy and safety may be jeopardised.

"In the parallel system adopted by the Board of Trade the size of the conductors for a given number of lamps is determined by the specific relation between the resistances of the lamp and dynamo respectively. The higher the resistance of one, and the lower the resistance of the other, the smaller may be the conductors. As, for example, in the Edison system, the lamp has 140 ohms resistance when burning, and the dynamo machine but 3-1000 of an ohm. The wires, therefore, for a given number of lamps may with safety be very small. Supposing a consumer were to introduce upon his premises, provided with conductors for such lamps, one of the many other forms of lamps of lower resistance and economy, the conductors would then be inadequate, and a consequent loss of energy and increased risk of fire would ensue.

"These considerations lead to the question of the provisions proposed by the Board of Trade for testing the current on the mains by a parochial electric inspector. The companies are strongly of opinion that any tests made should, in the interests of the public, consist of an examination and test of the light supplied, and not of the methods of producing that light. The only object of testing the current would be to see that the potential is not beyond the safe limits prescribed by the Board of Trade. The Edison system, for example, will enter the house at a pressure of 110 volts. If the pressure be greater than this, the lamps would burn out, and the company would lose their custom. If the pressure be lower than 110 volts, the lamps would burn at a dull red, and the company would likewise suffer the loss of its custom. Moreover, one of the cardinal points on which the Edison system rests is the continuance of the current on the mains day and night, without the intermission of a single minute for testing. The tests are made while the current is on the mains. The instruments for doing this are the invention of Mr. Edison and his assistants, and it is not likely that the parochial electric inspector of the future will possess the qualifications either to invent the instruments or to use them when invented, unless he is taught to do so by the Edison Company. The inspectors appointed under the Adulteration Acts are, no doubt, well fitted for the purposes for which they are employed, but the inspection of a great electric light system is a much more difficult matter, and one that would be better undertaken by the skilled officers of a Government department, carefully selected, than by a parish authority, who has everything to learn on the subject, elected by an elective vestry. It is necessary to speak plainly in this matter, and the companies' view of the parochial electric inspector of the future is that while the public will not be benefited by any inspection or testing of the current, it would be benefited by a photometrical inspection of the light supplied and a record of potential at the central station and at various points throughout the districts being furnished either to the Board of Trade or to the parish authorities."

THE EASTBOURNE ELECTRIC LIGHT COMPANY.

The second ordinary general meeting of this Company was held at Eastbourne, on Saturday, the 17th inst., Mr. G. Boulton in the chair. After the usual preliminary business,

The CHAIRMAN said a copy of the report and the accounts had been sent to each shareholder, and, he presumed, they would be taken as read. From the latter it appears that in the capital account the capital received on 491 shares was £4,910; when the payment for machinery and plant, rent, salaries, &c., amounted to £4,000 8s. 6½d., leaving a balance on capital account of £909 11s. 5½d. The assets and liabilities on capital account showed assets: £2,269 11s. 5½d; liabilities, £4,014 1s. 8d. From the revenue account it appears that the receipts were £744 12s. 3d., including £507 10s. 5d., the balance charged against capital, to be reimbursed out of revenue: and the payments were an equal amount. From the report it appears that the income of the Company from public and private lighting now working amounts to £1,306 per annum, which is sufficient to cover all the present working expenses.

The CHAIRMAN (continuing) said it was his duty to move the adoption of the report and accounts of the past year. He thought, looking at the satisfactory nature of the report, he had a very light duty to perform. He did not know that he could say more than the report said for itself. Within twelve months they had lighted a great portion of Eastbourne, and had contracts for lighting up other parts of the town. With a view of introducing the incandescent system of lighting they had taken Mr. Gosden's brewery in Junction-road. They had received many applications for incandescent lamps; and the directors firmly believed that if the incandescent system of lighting were introduced the Company would be able to make a large profit, and to pay a good dividend. But at present they had not sufficient money to start it. Before starting such a system they must have more capital. They could light with their present capital and plant many more arc lamps than were being worked at present: and as they were paying the working expenses every additional arc lamp they worked would mean new profit for the shareholders. But, he was afraid, they would not make sufficient profit out of arc lighting alone to pay such a dividend as they should like to receive. And, therefore, the directors wanted permission to issure more capital—say from £3,000 to £5,000 to enable the Company to start a system of incandescent lighting. The engineer had reported to him that during the year eight and a-half miles of cable had been laid in just over four miles of pipe or tubing. They had now 36 lamps, and a contract with the local board for seven others, which would make altogether 43 lamps. They had also entered into a contract with the Waterworks Company to light up their new engine house.

The report and balance-sheet were adopted.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on Thursday at St. Michael's Hall, George-yard, Lombard-street, E.C., Sir Henry Drummond Wolff, M.P., in the chair.

Mr. R. M. CUNNINGHAM (the secretary) having read the notice convening the meeting,

The CHAIRMAN said the object of the meeting was to confirm the resolutions passed at the previous meeting, and he had very little to say, except that Mr. Price had written to the directors to say that he still retained his opinion with regard to the desirability of not dividing the shares in the manner proposed. It might be satisfactory to the shareholders to know that the traffics were still going on very satisfactorily.

Mr. HERRING then moved the confirmation of the resolutions passed at the previous meeting, having for their object the division of the shares into preferred and deferred shares.

Mr. SUTTON seconded the motion.

Mr. PRICE said that when this matter was originally proposed all the shareholders at the meeting excepting three supported him in his opposition to it. The effect of the division of the shares would be to lead to very wide speculation, and it would lead to unfair transactions taking place. In the cases of Brighton "A," South Eastern "A," and Sheffield "A," any one could see the violent fluctuations that took place on the Stock Exchange, and that led to the detriment of the companies, and to the boards of directors, who managed them. In many cases inferences were drawn that some charges which ought to go against dividend were put off, or, on the other hand, some charges were put to revenue which ought not to be. He asked what advantage it would be to the Company to divide their shares. They were not increasing the capital of the Company one *iota*; they were not adding to the revenue of the Company one *iota*, and were doing no good to the Company, but, in fact, injuring it, whilo the operation would increase the clerical work of the office by 200 per cent.

Dr. GUESDON pointed out that the effect of the operation would be to reduce the qualification of the directors, and having referred to the number of shares held by the Board, he moved an amendment having for its object the decreasing of the voting power of the deferred shareholders.

The amendment, however, fell to the ground for want of a seconder.

The resolution was then put and carried, six voting for and two against it.

The CHAIRMAN having mentioned that the Board held a large number of proxies, the proceedings terminated in the usual manner.

SLIP

ELECTRICITY IN OUR HOMES.—The first of a series of articles on this subject, from the pen of Mr. John Munro, will be found in this month's *Good Words*.

REPAIR OF THE DIRECT SPANISH CABLE.—The Direct Spanish Telegraph Company's cable communication with Spain, *viâ* Bilbao, is now again fully restored.

TO BE WOUND UP.—A petition was to be heard before Mr. Justice Fry, on Friday, the 16th inst., for the winding up of the Electric Light Syndicate, whatever that may be.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of March, 1883, amounted to £32,970, against £33,677 in the corresponding period of 1882.

ELECTRIC LIGHTING FOR LEWISHAM.—The Jablochkoff Company have asked permission of the Lewisham District Board of Works to their obtaining a license under the Electric Lighting Act.

THE ROYAL SOCIETY.—At the meeting of this society on Thursday last the following paper was to have been read by Professor Horace Lamb, viz.:—"On Electrical Motions in a Spherical Conductor."

CHINESE TELEGRAPH RATES.—The *Journal Télégraphique* announces that the Chinese Government have recently raised the tariff for telegrams between Shanghai and Nankin, from 1·40 francs per word to 1·50 francs.

TASMANIA.—The Industrial Exhibition was opened at Hobart on February 6 by the Governor with much ceremony. The building, which was crowded at night, was illuminated by the Brush light.—*Colonies and India.*

NEW COMPANY.—A company has been formed in Newark, New Jersey, U.S., under the title "The American Electric Storage Company," to work the patents of Mr. Nathaniel S. Keith, of New York, for storage batteries.

DIRECTORSHIP OF SPANISH TELEGRAPHS.—Senor L. del Rey has been appointed Director-General of Posts and Telegraphs in Spain, in place of Senor Candio Martinez, who has been promoted to the office of State Counsellor.

SUBMARINE CABLES TRUST COUPONS.—The Submarine Cables Trust give notice that the coupons due on the 15th inst. will be paid on and after Monday, the 16th instant, by Messrs. Glyn, Mills, and Co., 67, Lombard-street, E.C.

SOCIETY OF TELEGRAPH ENGINEERS.—The next meeting will be held at 25, Great George-street, S.W., at 8 p.m., on Thursday, the 12th April, when a paper will be read "On Microphonic Contacts," by Shelford Bidwell, M.A., LL.B.

HONOURS FOR A TELEGRAPHIST.—The *Gazette* announces that the Queen has given directions for the appointment of Mr. Charles Clarke, Chief of the Egyptian Telegraph Department, to be a Companion of the Order of St. Michael and St. George.

PERSIAN TELEGRAPHS.—The Indo-European Telegraph Company state that, the cables of the Indian Government in the Persian Gulf being now restored, they are prepared to accept messages for transmission between this country and India, China, &c.

ELECTRIC LIGHTING AND THE HAMPSTEAD VESTRY.—The Hampstead Vestry have called in Mr. Williams, of Palace-chambers, St. Stephen's, to report and advise on the provisional order applied for by Messrs. Ferranti, Thomson, and Ince for that district.

THE MAXIM-WESTON ELECTRIC COMPANY.—We understand that this company have contracted with the Science and Art Department to light Bethnal Green Museum throughout, also with the contractors for the Tilbury Dock Works, to enable them to work continuously by night and day.

ELECTRIC LIGHTING IN RESTAURANTS.—The Electric Light Supply and Fitting Company are installing 80 Swan lamps in Messrs. Browne and Martin's restaurant in Dacre-street, Westminster, S.W. The current is supplied by a vertical Franklin dynamo, driven by one of E. R. and F. Turner's engines.

THE TELEPHONE IN NOTTINGHAM.—The Watch Committee of the Corporation of Nottingham have instructed Mr. Fry, manager of the National Telephone Company's Exchange in that town, to erect a series of fire alarms at various points. Several have already been erected; they communicate with the station and the fire stations.

THE NEW ARMY TELEGRAPH CORPS.—It is stated that the commanding officer of the 24th Middlesex Rifle Volunteers (Post Office Corps) is asking for men who have had experience in artillery and cavalry regiments, to act as drivers to the recently-acquired telegraph van. This completes the equipment of the Postal Telegraph Corps, which now numbers more than 150 men.

ELECTRIC BELLS.—Mr. Gent, of Leicester, is exhibiting at the Building Exhibition now being held at the Agricultural Hall a new method of arranging the electro-magnets of electric bells, by means of which he obtains more power with a given current. Mr. Gent's plan consists in placing the electro-magnets horizontally and the armature above them, instead of at the side and at an angle, as is usually the case.

ELECTRIC LIGHTING IN PARIS.—On the occasion of the annual *conversazione* of the French Physical Society, the rooms of the Society of Arts, where it was held, were brilliantly illuminated by means of Edison and Swan lamps and accumulators. The transmission of power was also illustrated by means of a Gramme machine, which was supplied with current by accumulators. These latter were supplied by the French Electrical Power and Storage Company. M. Trouvé also exhibited some of his new bichromate of potash batteries at work.

THE EDISON SYSTEM IN PARIS.—*L'Electricité* says:—"On the 20th March M. Louis Rau, manager of the Société Edison, gave a brilliant reception in his *salons*. Edison lamps replaced candles and gas burners throughout. On the commencement of the *cotillon* towards 2 a.m., each of the lady dancers was presented with a bouquet, in the middle of which shone an incandescent lamp. After a mazy valse, the bouquets were deposited on a daïs, where they formed a grand constellation of flowers and light. The lamps were fed by means of batteries devised by M. Trouvé."

THE EASTERN EXTENSION TELEGRAPH COMPANY.—This company state that their accounts to the 31st of December last show, subject to audit, a balance of profit of £109,355, after payment of three interim dividends and a bonus for the first half of the year. The directors now propose to pay on the 18th inst. a final dividend of 2s. 6d. per share, together with a bonus of 2s. per share (both free of income-tax), making, with previous distributions, a total payment of 6½ per cent. for the year 1882. A balance of £64,411 is to be carried to the reserve fund, which now stands at £351,133.

TELEPHONIC EXTENSION IN FRANCE.—A telegram from Paris, dated Tuesday, states that telephonic communication is receiving rapid development there. From the 1st of July

Digitized by Google

next telephones will be annexed to all telegraph offices in Paris, and the chief ones in the provinces, as well as at the leading railway stations. The charge to those using them will be 25 centimes, and for this sum five minutes will be given for the reception and transmission of messages. The apparatus will be established in private residences at an annual subscription of 170 francs in Paris, and 200 francs in the provinces, about £7 and £8 respectively.

Arrest of a Company Promoter.—A Reuter's telegram from Paris, dated April 4, says:—"At the request of the Belgian Public Prosecutor M. Simon Philippart was arrested here yesterday on a charge of falsifying the accounts of his bank. The Belgian Government has demanded his extradition." Another telegram says:—"M. Simon Philippart, who has lately promoted several electric lighting companies, has been arrested at his office in the Avenue Opera, at the instance of the Brussels authorities, who demand his extradition on a charge of forgery and of having obtained money by fraudulent pretences. The preliminaries necessary before his surrender are now being proceeded with."

Electric Lighting at Brighton.—On the occasion of a fancy dress ball, held in aid of the Brighton *crèche* on Wednesday last in the Pavilion, the banqueting hall, in which the dancing took place, was lighted throughout by Swan lamps. The lighting was carried out by Mr. Magnus Volk, who has been entrusted with the work of extending this means of illumination throughout the whole building as a permanency. He has made such progress with the "wiring" that it is hoped the lighting will be completed in about three weeks time. Swan lamps will be used throughout, the current being supplied by a Siemens dynamo. The power will be afforded by a Robey semi-fixed engine, situate in the Corporation Yard.

The Edison System in the House of Commons.—The Edison installation at the House of Commons started running this week. The lights are distributed throughout the dining room and library. Sixteen electroliers, each containing a group of sixteen lamps, are in use, the current being supplied by two 250-light "K" dynamos, similar to that illustrated in our issue of the 24th ult., p. 441. The lamps can, if necessary, be fed by one ot these machines should any accident incapacitate either of them. The dynamos are driven by an Armington and Sims engine, of similar make to that described in our issue of the 24th ult. A cable, 150 feet long, runs from the engine room to the lamps. We wish the company every success with their contract, which, we understand, lasts till the end of the Session.

Electric Lighting and the Czar's Coronation.—*The Times'* correspondent telegraphs from St. Petersburg under date March 30, as follows:—"At Moscow the preparations for the coronation are making rapid progress. For four nights the great belfry tower of iron was splendidly illuminated by electricity by way of an experiment. No fewer than 4,000 Swan incandescent lamps cover the cupola, and 120 electric lamps of Russian invention outline the cross. All the principal churches are also to be illuminated with ordinary lights from foundation to spire. The assistance of foreigners in the work is to be entirely dispensed with if possible; and no English illuminating or pyrotechnic firms will be employed on this occasion, as they were at the coronation of Alexander II. The firework displays are to be conducted by artillerists and engineers, independently of all extraneous aid."

The Simoom and Dust Storms.—In a paper recently read before the Meteorological Society, Dr. H. Cook, F.R.G.S., described the dust storms which take place in Beloochistan, North-west India, and stated that he considers them to be due to an excess of atmospheric electricity. With regard to the simoom, which occurs usually during the hot months of June and July, it is sudden in its attack, and is sometimes preceded by a cold current of air. It takes place at night as well as by day, its course being straight and defined, and it burns up or destroys the vitality of animals and vegetable existence. It is attended by a well-marked sulphurous odour, and is described as being like the blast of a furnace; and the current of air in which it passes is evidently greatly heated. Dr. Cook believes it to be a very concentrated form of ozone, generated in the atmosphere by some intensely marked electrical condition.

The Wire Question in America.—We take the following items of information from the *Sanitary Engineer*:—"The City Councils of Philadelphia, on the 15th ult., amended the ordinance to permit the Baltimore and Ohio Telegraph Company to place wires through the city, so that the company is required to lay the wires underground in the built-up portions. The mayor has made it known that he will veto any ordinance granting the right to erect poles in the streets.—Captain F. U. Greene (U.S. Engineers), after inspection of systems of underground electric wires in Boston and New York, is in favour of prohibiting the further erection of poles in Washington. He recommends that experiments be made with the fire alarm wires to test an underground system less expensive than those now usually employed, and he recommends that estimates be submitted to the next session of Congress for placing all fire alarm wires underground, and a Bill be prepared compelling all electric wires to be put underground at an early date.

Electric Light in an Indian Mill.—The Egerton Woollen Mills, lately erected at Umritsar, Punjaub, have adopted the electric light for their premises. The installation consists of a 16-light Brush dynamo machine and 16 arc lamps, throughout the mills and compound. The installation is very successful. The looms, carders, and other machinery are well lighted. The natives admire the light very much, and call it "Bidjerley" lightning. They are able to work all night with perfect ease, and are arranged in two gangs, one gang working from 1 p.m. to 10 p.m., and the other from 3 a.m. till 12 noon. All colours of the wools are perfectly seen. The power is obtained from a Bolton turbine. The water is diverted from a canal near, and afterwards used for irrigation purposes. The cost of maintainence for the lights, therefore, is—carbons and wages of a native to trim the lamps and attend machines, 10 rupees per month (16s.). A saving is also effected on insurance. The work was carried out by the Eastern Electric Light and Power Company, under the superintendence of Mr. E. W. Lancaster, engineer in charge, who successfully carried out the lighting at Rupar, on the opening of the Sirhind canal by H. E. the Viceroy.

Electrical Engineering in America.—We take the following from the *New York Mail and Express* of March 16:—"In reviewing the report of the plans of the Columbia College authorities the other day, reference was made in these columns to a school of electrical engineering, which President Barnard said was needed to extend the scope of the college. On Tuesday of this week a meeting of the committee appointed to consider the project was held, Mayor Low, of Brooklyn, being the chairman, and definite plans were proposed for the immediate establishment of such a school. Estimates had been obtained from Mr. Edison as to the cost of the necessary 'plant,' and it was said by

Digitized by Google

that gentleman that 15,000dols. would cover the first cost. After that the school could be kept up for 25,000dols. a year. It is proposed to ask the different telegraph and telephone companies to supply the plant and contribute 12,000dols. a year to the support of the school, which would be of great help to them in furnishing, what is now difficult to get, trained electrical engineers, such as they need for the successful operation of their business. In case this request is granted by the companies the school will at once be established, the present professors taking a share of the work, and new professors being engaged so far as necessary. We hope the committee will be successful. Such a school is needed, and its establishment would be a good beginning in the building of that great university at which the college authorities are aiming."

Charing-cross and Waterloo Electric Railway.—The prospectus of a company which has been formed with the above title has just been issued. The proposed capital is £100,000 in £10 shares. The object of the undertaking is to construct and work an electric railway from Charing-cross to Waterloo, a Bill for which was recently obtained, as mentioned in these columns some weeks since. The line will pass under the Thames through iron caissons. The work of construction will commence near the northern end of Northumberland-avenue, opposite the Grand Hotel, and be continued through an arch under that avenue and the Victoria Embankment. Of that arch sixty feet under the Embankment have already been constructed. The railway will pass under the Thames, and again through an arch under College-street and Vine-street, and terminate at Waterloo Station, where it will be directly connected with the platforms of the London and South Western Railway, with a separate approach from the York-road. The line will be double, and worked by means of a stationary engine at Waterloo, transmitting the power to the carriages, which will run separately, start as filled, and occupy about 3½ minutes in the journey. A tender has been accepted for the construction of the railway, to be ready for opening within eighteen months from the commencement of the work. A contract has also been made with Messrs. Siemens Bros. and Company to provide and erect all requisite electrical machinery, rolling stock, and apparatus not included in the before-mentioned tender. Messrs. Kellett and Bentley have the contract for the line for the sum of £80,000.

Legal.—The Brush and Gramme Dynamo.—On Wednesday last, before Mr. Justice Watkin Williams and Mr. Justice Mathew, in the case of the British Electric Light Company and the Electric Power Company *v.* the Anglo-American Brush Electric Corporation, Mr. Moulton moved on behalf of the defendants on appeal from an order of Mr. Justice Hawkins, made at Chambers, affirming one made by a Master refusing to order the plaintiffs to give security for costs. The learned counsel said he relied upon an affidavit made by Mr. Cordner, the general manager of the defendants, who stated his belief that neither of the plaintiff companies had any assets available for the payment of the costs of this action in the event of the verdict being in favour of the defendants. Mr. Cordner's affidavit was, further, to the effect that the Electric Power Company had a capital of 5,007 shares of £10 each, of which all but seven had been fully paid-up, and that he believed they were without either property or assets to answer the costs of this action; that the British Electric Light Company had a nominal capital of £100,000, in shares of £10 each, of which, on July 27, 1882, 7,221 had been issued and fully paid-up, with the exception only of a sum of £610, due on calls not paid. Mr. Cordner also swore that he had been informed and believed that the British Electric Light Company (Limited) were carrying on this action by the aid of funds subscribed by their shareholders and others. The learned counsel said that the costs of the defendants had already amounted to £1,800, and would amount to a further sum of at least £2,000, as the litigation, involving, as it did, the whole question of the patent rights in dynamo machines, must necessarily prove to be of the most expensive character. The Court dismissed the appeal, with costs, without calling upon Mr. Carpmael, who appeared for the plaintiffs.

Electric Lighting for Dundee.—The following is some further information which has been made public with reference to the lighting of Dundee by means of Brush lamps:—At a special meeting of the Dundee Gas Commissioners, held a day or two since, Provost Moncure explained that the first condition of an agreement that had been come to between a committee of the commissioners, when recently visiting London, and the Brush Company, was that the order promoted by the Gas Commissioners for lighting the town should be withdrawn. By the other conditions the Brush Company would get four years to make experiments; but if they did nothing in that time in the way of erecting works and getting apparatus for lighting the compulsory area, then their order would entirely lapse. This would secure the making of experiments without the commissioners being put to any expense, and if experiments were made in the four years, then the order would extend over 15 years, instead of 21 as in the Bill. After that period had elapsed, the company were obliged to dispose of their works to the Gas Commissioners if the latter desired them, and on the terms laid down in the Commissioners' Act. If the Gas Commissioners did not want then to purchase the works, the company would go on and supply the light for seven years, when the commissioners would have the opportunity of again purchasing if they desired. If no purchase was made, then the company would go on supplying the electric light, but with a similar break at the end of each seven years. It was also a condition that the company would light the streets when requested by the Police Commissioners, on terms to be agreed upon. The Gas Commissioners considered the terms of the agreement very favourable, as it prevented monopoly, and gave the commissioners an opportunity to step in at any time and take the lighting into their own hands. The agreement was approved of, and remitted to the committee to get it carried out.

On the Material Particles in Electric Sparks.—We take the following abstract of a paper by Dr. Friedrich Wächter, in the "Sitzungsberichte der kaiserlichen Akademie der Wissenschaften," Vol. LXXXV., March, 1882, from the abstract of papers in *Foreign Transactions*, &c., published by the Institution of Civil Engineers.—"In two former communications to the Vienna Academy, Professor Reitlinger and the author had endeavoured to prove that the glowing particles of the electrode, which constitute an electric spark, emanate entirely from the positive electrode. On the other hand, the experiments of Plücker, Gassiot and others, show that, under certain circumstances, the loosening and projection of the particles takes place at the negative electrode. The object of the present paper is to discuss this apparent inconsistency, and to consider the difference between the electro-positive and electro-negative loosening of the particles of the electrode. Only the discontinuous sparks produced by a friction machine, or by the secondary circuit of an induction coil, are considered, the formation of a continuous electric arc by the heated particles of the positive electrode

Digitized by Google

being well known in the case of galvanic currents generated by a dynamo machine or ordinary battery. It has generally been stated in text books that sparks produced electro-statically possess the same characteristics, whether the discharge be of positive or negative electricity; but the study of Priestley's ring figures, Lichtenberg's figures, and the deflection of the particles by a powerful magnet, show conclusively that the two phenomena are distinct, and marked by essential differences. The author summarises the results of his investigations on discharges through a gaseous medium briefly as follows:—1. The projection of the anode particles takes place in atmospheric air under a pressure of 4,500 to 10 millimetres of mercury; the projection of the particles of the cathode could only be observed for pressures varying from 63 to 0·005 millimetre. 2. The quantity of particles loosened from the electrodes, in equal times and under similar circumstances, diminishes with decreasing atmospheric pressure for the anode, but increases for the cathode. 3. The anode-particles are projected considerably further than the cathode-particles under the same conditions. (In the case of a pressure of 63 millimetres, about 3,400 times as far.) 4. The anode-particles, uninfluenced by the pressure of the air, always proceed from a relatively small surface; the cathode-particles, on the other hand, are projected from a surface always increasing in area as the pressure diminishes. (The area in the latter case reaches as much as 10,000 times that in the former.) 5. The anode-particles leave always from a determined position on the anode, viz., the point lying nearest the cathode; whereas the cathode-particles proceed from the whole surface of the cathode. 6. The projection of the anode-particles is favoured by an electrode bent or pointed in form; the projection of the cathode-particles by a clean surface, free from oxidation. 7. The direction of motion of the anode-particles is determined by the relative position of the cathode, since they move towards the cathode in the direction of the current along the line of least resistance. The cathode-particles always proceed normally to the cathode surface, uninfluenced by the relative position of the anode and the direction of the electrical current. 8. The anode-particles can move in all conceivable curved paths, while the cathode particles describe straight lines, and are not capable of moving in a curved line. 9. The anode-particles are deflected by a magnet, as if they were diamagnetic substances; the cathode-particles are affected like paramagnetic bodies. 10. The anode-particles are transferred both in a luminous and non-luminous condition; the cathode-particles only in a non-luminous condition. 11. The anode-particles are of measurable size, and are apparently loosened by some mechanical impulse; the cathode-particles are indefinitely small, and seem to originate from a process of vaporisation. 12. The projection of the cathode-particles is certainly promoted by warming the electrode, whereas this cannot be asserted with safety with regard to the anode-particles. 13. The cathode-particles are the vehicles of the electric current from the electrode to the molecules of the gaseous medium. This is not the case with the anode-particles. 14. From the experiments of Wiedemann and Rühlmann, it appears that a greater electrical tension is necessary for the projection of the anode-particles than is required for the cathode-particles. These facts prove, in the opinion of the author, that the difference between the two kinds of electricity cannot be successfully explained by the assumption of a reversal of conditions, which can be expressed by plus and minus, but involves an essentially qualitative change."

THE MEASUREMENT OF ELECTRICITY.—This was the title of a lengthy paper read by Mr. J. N. Shoolbred, M.I.C.E., before the Society of Arts, on Wednesday evening last. Dr. C. W. Siemens, F.R.S., occupied the chair, and the audience was a large one. The paper of necessity went over a good deal of old ground, and described a number of meters which have already been dealt with in our columns; we shall, therefore, content ourselves with giving the more salient points of Mr. Shoolbred's communication, leaving those of our readers who care to do so to fill up the gaps by consulting the *Journal of the Society of Arts*. Having defined the terms, "electricity," "magnetism," and "electro-magnetism," Mr. Shoolbred passed on to the various units, and the manner of their adoption. When speaking of the unit of "price," which the Board of Trade suggest should be based on the energy contained in a current of 1,000 amperes flowing under an electromotive force of one volt during one hour, or, in other words, 1,000 volt-ampere-hours, Mr. Shoolbred said:—"The ampere-hour is another way of saying 3,600 coulombs of quantity of electricity supplied. It may also be of interest to state in other, and perhaps more conventional, terms the equivalent of the amount of work implied in the above unit.

Work done, or Energy Expended.

1,000 volt-ampere-hours =
- 10^{10} erg hours.
- 3,600,000 volt-coulombs.
- 3,600,000 joules.
- 1,000 watt hours.
- 2,645,000 foot-pounds.
- 366,840 kilogrammetres.
- 1·35 force cheval-heures.
- 1·34 horse-power hours.

Put in terms more in accordance with actual practice, the above unit might mean the supply for one hour of a current of 10 amperes with an electromotive force of 100 volts, or of a 5-ampere current with an E.M.F. of 200 volts; or, again, a 10-ampere current at 200 volts for only half an hour, and so on, provided that the product of the three factors is always 1,000." The author then dealt with the instruments required to measure electric energy, and stated that it was only such as were "furnished with means for continuously integrating or recording the successive progressions of the supply, or instruments to which such recording apparatus can readily be attached," that came properly within the scope of his paper. There must, Mr. Shoolbred insisted, be a continuous record both of the pressure and current, either separately or combined. He then proceeded to describe some "non-registering instruments" or current measurers only, premising that any current measurer may be converted into a recorder of quantity or a coulomb-meter by the integration of the time during which the current has flowed. Under this head, then, he placed Siemens's electro-dynamometer, Obach's tangent galvanometer, Cardew's low-resistance galvanometer, Ayrton and Perry's ammeter, and Sir William Thomson's current galvanometer; under the head "Pressure Measures," he classed and described Ayrton and Perry's voltmeter, Sir William Thomson's potential galvanometer, and Siemens's torsion galvanometer; then followed Ayrton and Perry's power meter, and Siemens's watt-meter, which were identified as "power or energy meters;" and, lastly, "Resistance Measurers," under which head Ayrton and Perry's ohmmeter appeared alone. Turning next to "Registering Instruments," Mr. Shoolbred thought that they might be divided into two classes, 1st, quantity, or coulomb-meters; and 2nd, energy, or work meters. The first of these classes again could be split up into A, those based on electrolytic action, and B, those which were mechanical in principle. Under Class 1 A, the following

Digitized by Google

meters were described, viz.:—Edison's and Sprague's. Under Class 1 B, came Hopkinson's and Boys's. Finally, under Class 2, the author dealt with Boys's energy meter, Deprez's ditto, and Ayrton and Perry's erg-meter. Mr. Shoolbred concluded with the following words:—"It is probable that the supply of electricity in a town will be carried out at a certain defined standard pressure or electromotive force, which will be guaranteed to the consumer; and to assure the fulfilment of this condition special steps will be taken by the local or other authority. The consumer need, therefore, but concern himself, as far as the supply he receives and has to pay for, with the quantity of electricity which he has made use of. In fact, the meter he makes use of to record it may be a coulomb-meter. The work, or energy-meters will not be needed for general application, but only in special cases. The brief review just made of the subject of the measurement of electricity, as well as of some of the instruments employed in it, will, it is hoped, tend to show that measurement of a very precise nature can be made; more so, indeed, than perhaps in any branch of physical science. Also, that a large number of very effective instruments already exist."

Sixpenny Telegrams.—In the House of Commons on Thursday last, Dr. Cameron moved "That the time has arrived when the minimum charge for inland postal telegrams should be reduced to 6d." The hon. member supported his motion in an able speech, in which he brought forward a number of arguments in its favour. Several other hon. members joined in the debate. We are compelled, however, to omit all mention of their speeches, owing to the pressure on our space, and must, perforce, confine ourselves to the following extracts from the answer made by Mr. Fawcett, the Post-Master-General. He said, that "It appeared to him that the proposed reduction could be reduced in three different ways. As his hon. friend had suggested, they might have a charge of one halfpenny a word with a minimum charge of 6d., addresses being charged for; or, secondly, as advocated by his noble friend who preceded him, they might continue the free addresses, having a minimum charge of 6d. for six words, and one halfpenny for each additional word. The third way was a simple one—to retain the free addresses and charge 6d. for the first six words, 9d. for twelve, and 1s. for twenty words. Unfortunately, each of those plans varied in costliness directly as their convenience. The first plan was the least costly and the least convenient. The second was considerably more costly than the first, and the third still more costly than the second. Therefore, in considering the matter, the Government would have to consider, when the change was adopted, what amount of revenue they were prepared to sacrifice for the convenience of the public. He wished to state as briefly as possible what were the estimates of the loss involved in the proposed reduction. He had had the assistance of two of the ablest officials of the Post Office in making the estimate, and he would give them the figures of the official who put the loss at the maximum. In the first year, if a rate of one halfpenny a word were adopted and addresses charged for, the loss would be, as stated by his hon. friend, £179,000. He estimated that the loss would rapidly diminish, and that in four years time the telegraph would yield as large a sum as at present. The second plan, which was favoured by his noble predecessor in office, would be much more costly. The estimate was in that case, that the loss, instead of being £179,000 in the first year, would be £150,000 more than that, or in other words, that the loss would be £320,000, which would bring the revenue down to little more than £40,000. But in stating the advantages which belonged to free addresses, and the disadvantages which would attach to charging for each word of the address, it ought not to be forgotten that the present plan was extremely wasteful. He thought there was some force in what was urged by his hon. friend, the member for Glasgow—that considering they had at the present time 5,900 telegraph offices, it showed but a small amount of business when they had only 80,000 telegrams a day, or an average of about 14 for each office. He thought, as he had stated on a previous occasion, that the shilling telegram was a prohibitory charge to a considerable section of the lower middle class." Criticising Dr. Cameron's figures as to the revenue derived by the Post Office from the telegraphs, Mr. Fawcett said that "He would give the House the revenue of the Telegraph Department, calculated on commercial principles, during the last three years, and they would at once see that that law of continuous increase (put forward by Dr. Cameron) did not, unfortunately, apply to that service. In 1880-1 the commercial profit from the service was £440,000; in 1881-2, it sank to £353,000; and during the present year, with an increased capital of £200,000, on which interest ought to be allowed, the commercial revenue was £363,000, or, reckoning £6,000 for interest, only about £4,000 instead of £50,000 better than the year previous. No doubt the falling off was due to the circumstance at which his hon. friend had hinted. The salaries of the telegraph *employés* had, he did not say by the pressure of the House, but certainly with the approval of the House, been increased. He did not regret that increase. He thought the extra pay they received was due to them, and if it had not been so he could only say that no number of memorials would have induced him to recommend the Treasury to make such a sacrifice of revenue. What, then, was the financial position of the telegraph service? Their capital might be taken at ten and a-half millions; £353,000, the profit on the year 1881-2, would represent an interest of $3\frac{1}{4}$ per cent.; and the profit on the present year represented about $3\frac{1}{3}$ per cent. Therefore, from that point of view, the telegraph service might be considered at present to be just a paying concern, yielding the current rate of interest upon the capital expended. But there was another consideration on which he should not be very frank if he did not say a few words. The capital of ten and a half millions represented the sum that was paid by the State for the telegraphs. But, owing to the blunder committed by the Government and sanctioned by Parliament—for both the Government and Parliament were alike responsible in the matter—they were saddled with what might be regarded as a useless capital expenditure of three and a half millions, because he was told on the highest authority, by which great pains had been taken to investigate the subject, that if instead of the ten and a half millions that were paid for the telegraphs, £7,000,000 had been paid, that would have been a large, if not an extravagant sum." Mr. Fawcett concluded by saying that "whether the day came soon or came late, the very moment they received an instruction from those in superior authority, either from the Government or from his right hon. friend the Chancellor of the Exchequer, that the revenue was open to lose for one year £170,000, and for four years an aggregate sum of £450,000, that news would be welcomed at the Post Office, because all that they considered they had to do was to make what revenue they were ordered to make for the Government, at the same time giving the utmost possible facilities to the general public, either postal or telegraphic." The result of the debate was that the motion was carried by 68 votes to 50.

THE (ELECTRIC) CONDUCTIVE AND INDUCTIVE CIRCUITS GEOMETRICALLY ILLUSTRATED.

BY F. C. WEBB, M.I.C.E.

(CONCLUDED FROM PAGE 393.)

The Wheatstone bridge is shown in Fig. 57. A E is the potential at the battery pole attached to bridge, the other pole being to earth. A B and A C are the ratio branches of the bridge, and the galvanometer G is connected between C and B. When balance is obtained the potentials at C (C D) and B (B F) are equal. Therefore, if B L be the resistance plugged to obtain balance, then C M will be the resistance that is being measured. Fig. 58 shows a bridge "out of balance." The resistance B L has been made too great for the unknown resistance C M. The potential at B becomes greater than that at C, and there is a current, therefore, from B to C, through the galvanometer, shown by the inclination of the line D F. But the potential B F is still less than the potential would be at B if, with B L in circuit, that resistance was properly balanced by a resistance between C and earth. This

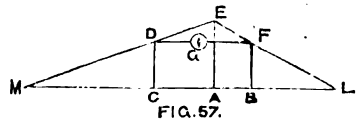

FIG. 57.

gives a steeper inclination to the potential lines in A B (E F), showing a greater current in that branch and a less steep potential line (F L) in B L, showing a decrease of current in that branch. In the same way C D is less than before; consequently, D E is steeper than before, and M D is steeper still, for it is the resultant of the two currents represented by the inclinations of D E in C A, and *illustrated* by the inclination of the line D F in the galvanometer. This latter line does not actually represent by its inclination the current in the galvanometer, because the length C B does not represent the resistance of the galvanometer. Nor do the proportionate inclinations of any of the lines show the correct proportion of current, as they are not worked out, but only drawn, of *greater* or *less* inclination, according to the evidence of the case.

Inductive Circuits.—The term "inductive circuit" is one I introduced some twenty years ago, when showing the applicability of Ohm's law to problems of electrostatics. It will be seen that, wherever accumulation of electricity occurs on the surface of a conductor attached to one pole of a source of

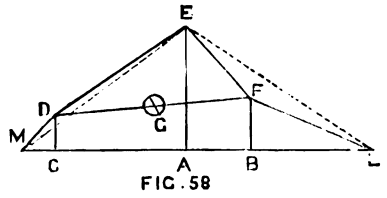

FIG. 58

electricity, the quantity that can be accumulated is dependent on the geometrical dimensions and the specific capacity for induction of the dielectric separating that surface from the surface to which the other pole of the source is attached. Thus, to take the simplest form, suppose a battery having one pole attached to a hollow sphere, and the other pole attached to a sphere placed concentrically within the hollow one. Then all the inductive effect would go on between the outer surface of the inner sphere and the inner surface of the outer sphere, and the quantity that would be accumulated would depend on the dimensions of the spheres and the nature of the dielectric separating them. We have an inductive circuit having only one resistance, namely, the shell of dielectric separating the two spheres. If we have two or more successive resistances in the circuit, then the quantity accumulated on any one of the surfaces depends on the *total* resistance of the inductive circuit.

Thus, if each pole of a source was connected to a sphere, each contained in a hollow shell, and the two shells are joined by a conductor, the quantity accumulated on any one surface will be inversely proportional to the *sum* of the two resistances—or, generally stated:* "*The quantity of electricity on any one surface of an inductive circuit composed of successive resistances will be, with a given source, inversely as the sum of all the successive inductive resistances in the circuit; and the quantity on each surface is the same throughout the whole circuit, but opposite in name on any two successive surfaces.*"

Thus, if a given battery has one pole attached to one plate of a condenser and the other pole to the other plate, the quantity accumulated will depend solely on the dimensions and nature of the dielectric of that condenser, and if we placed a similar condenser, but of half the inductive resistance (*i.e.*, twice the capacity), the second one would accumulate twice the quantity. For we have only one resistance in the circuit, and when we halve that we double the quantity. But if now we have a source, S (Fig. 59), one pole of which, N, is connected to a condenser plate, A, the other plate of which, B, is connected to a plate, C, of a second condenser, the other plate, D, of which is connected to the other pole, P, of the source, then, if we alter the condenser D C to twice its size, as by increasing the plates D' C', we shall no longer increase the quantity in this new condenser to double what was contained in the first one, for we have not halved the *total resistance* of the circuit.

In the same way, if we have two submarine cables of similar pattern and different lengths with distant ends insulated attached to the poles of a source, then the quantities in each would be *equal*, and opposite in name, but this quantity would depend on the total resistance of the inductive circuit. The quantity in either could never equal the quantity that

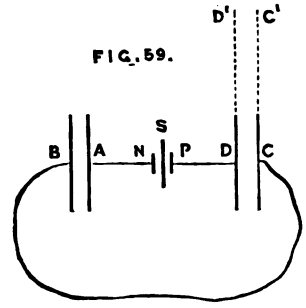

FIG. 59.

would be accumulated in one if that was the only resistance in the circuit. When the two are equal in resistance the quantity will be exactly half in each of what the charge would be if the other was cut out of circuit. And if one remains constant, and the other be constantly increased in length the quantity in the smallest will constantly increase towards (but can never equal) the charge that it would receive if the other did not exist.

This can be illustrated geometrically; but for this we have here to represent the *capacities* of the cables instead of their *inductive resistances*, and as the pattern of the cables, *i.e.*, the internal and external diameters of the gutta percha envelopes are supposed constant, the absolute lengths will be proportional to and represent their capacities.

The problem is as follows:—To find the potential and charges in two wires B C and A F of different lengths (but similar in section) when attached at B and A to the two poles of a battery B A (the electromotive force of which = A O), whilst their distant ends F and C are insulated. Let B C and A D represent the capacities of the two conductors under equal conditions as regards inductive resistance to a common conductor *x* (for instance the sea, supposing the wires were submarine wires). Let A B represent the battery, and A O the electromotive force or potential when one pole, A, is insulated, and the other, B, to earth. Then if a wire, A D, similar to B C, existed at A D, the potential in B C and A D would be equal, and equal to half A O, and the charges A D E N and B G H C would be equal, but of opposite sign. Suppose A D were now prolonged to A F. Then must the potential in A F be less than in A D, and the potential in B C must rise so that the products of the capacity A F

* "Electrical Accumulation and Conduction" (1862), p. 87.

Digitized by Google

and its potential A K shall equal the product of the capacity B C and its potential B M; or, in other words, the value of the two charges must still be equal. But, further, the sum of the two potentials, under the new conditions, must remain the same, for otherwise it would indicate a change in the electromotive force. Join E G.

Join F E and draw D J parallel to F E. Join J G, and through L, where J G cuts A B, draw K M parallel to E G, cutting A E at K and B G, produced at M. Draw M P parallel to and equal to B C, join H P. Draw K Q parallel to and equal to F A, and join F Q. Then will K A be the potential in A F, and A K Q F the charge in F A, and B M will be the potential in B C and B M P C the charge in B C.

For since D J is parallel to F E, the △'s D A J and F A E are similar, and the angle D A E common to both,

therefore A J : A E :: A D : A F,

2ndly. A L : L B :: A J : B G, but B G = A E (const.)

therefore A L : L B :: A J : A E,

A L : L B :: A D : A F, { "Euclid," Book, V., Prop. 11.

but A D = B C,

therefore A L : L B :: B C : A F.

Again, the △'s A L K and B L M are similar, as ∠ K L A = ∠ B L M, and ∠ L A K = ∠ B M,

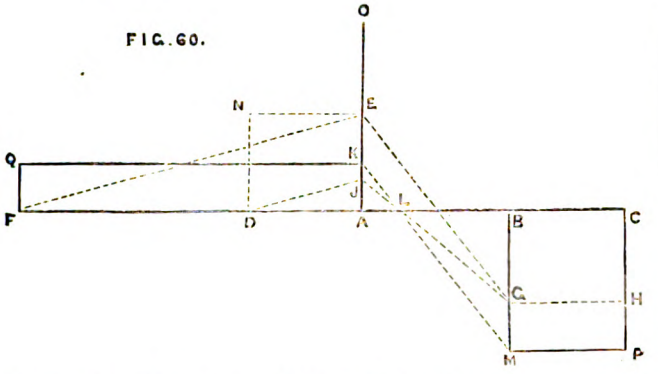
therefore K A : B M :: A L : L B,

but A L : L B :: B C : A F,

therefore K A : B M :: B C : A F, { "Euclid," Book V., Prop. 11.

or K A × A F = B C × B M, or the charges B M P C and A F Q K are equal.

FIG. 60.



Now, since K M is parallel to E G, and E K is parallel to G M, then E K M G is a parallelogram, and E K = G M, therefore A E − E K + B C + G M = E A + B C = the potential of A D and B C, but A E − E K + B G + B M = A K + B M = the potentials of A F and B C.

The sum of the potentials remains, therefore, unaltered, but if the potential at A was greater than A K, then, for the sum of the potentials to remain the same, the potential at B must be less than B M. The charge of A F would, therefore, be greater than A F Q K, and the charge of B C would be greater than B M P C. But it has been proved that A F Q K = B M P C; therefore, if potential A was greater than A K, the charges in A F and B C would be unequal, which, by the first principles of the case, it is asserted is impossible, since no generation of electricity of one name can take place without an equal quantity of the other being generated.

In the same way it may be proved that the charges would be unequal if the potential at A was less than K. Therefore, A K is the potential at A, and B M the potential at B, and the charge in A F is A F Q K, and the charge in B C is B C M P.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of March was 5,138, estimated to produce £4,500, against 4,300 messages, producing £4,123, in the corresponding month of last year. The traffic receipts for the month of December, estimated at £2,800, realised £3,068.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XVIII.

Before taking the discharge test, for which 50 or 100 cells may be used, the capacity of the cable may be found, and this should be determined for the time being, since it may vary a little. If the ordinary discharge method of finding it be employed it is most convenient to connect the standard condenser in the place of the cable in the figure, and to shift the plug in the battery commutator (here not shown) to the place for 10 cells; then to take the condenser discharge, and after substituting the cable take its discharge also. The connections then are ready for the insulation test, the only change necessary being the shifting of the plug in the battery commutator to the 50 or 100 cells place. A shunt is required in every instance to regulate the deflections. That for the condenser will most probably be on record, as the same condenser will be in use for all purposes. At any rate the capacity test will have been taken with the same arrangements, and our remarks in a previous number on capacity will suffice for any reference to the subject. The cable shunt, or that to be used for producing a readable deflection when the discharge is at full potential, will be smaller, or otherwise, according to the length of the section, so that, after taking the condenser reading, the shunt plug will be shifted to introduce a suitable branch resistance as shunt. An ordinary resistance box is the best form to employ

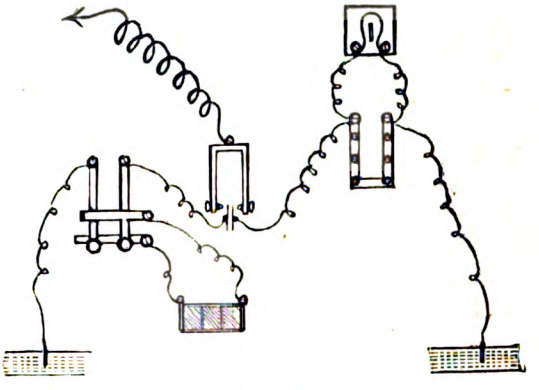


FIG. 39.—Insulation Resistance (Discharge Test).

even if there be a proportional arrangement for the galvanometer, as formerly explained. In a long section of cable we should probably have to use one unit only for shunt, perhaps less. The connections then being arranged for the cable test, the battery key will be clamped down to produce a negative charge. It is seen that no current can flow until the Lambert key, to which the cable is joined, comes into play, and by this arrangement the battery is always prepared for action. It will be noticed that we have not in this figure (Fig. 39) introduced a commutator for the galvanometer, though it may very probably be used, but it is not essential. In order to have as large a deflection as possible, it may be well to alter the zero on the galvanometer scale, and to turn the directing magnet till the spot is brought back to the end, giving it a range of the whole length. As 0 is in the centre this removal will bring the spot, say, to 400 at the left hand corner, and it must be remembered in valuing the deflections that the addition of these 400 divisions is to be made to all those that are passed over above the zero at the centre. Thus, if the deflection was 200 to the right of zero, the true value would be 600, and so on. It is not, however, always necessary to give so large a range; it must be determined according to circumstances. To continue the test, the battery key being down, the Lambert key is depressed on the side connecting with it, and the cable is thereby charged. This key is sometimes kept down for ten seconds, sometimes five, and then released, and the other side of the same key instantly touched down, when the cable is discharged through the galvanometer and a deflection produced, which is recorded. The operator

Digitized by Google

must be very careful in doing this to release the charging contact of the Lambert key before touching the other contact, though no appreciable interval must be allowed. One finger for each contact is most convenient for this purpose; the charging contact is set free by one and the discharge depressed by the other. The reason is that the cable may have no time to leak, and that the whole of the charge may be immediately extracted. For want of attention to this caution a beginner will very likely touch down the discharge side a trifle too quickly; in which case he will get no deflection, and will be puzzled, not being conscious of the act. We have now got the full potential, and have to determine the value after a certain period of leakage. To do this under the most favourable conditions the cable should be entirely free of charge; indeed, there ought not to be any left in it, or our deflection would have represented an imperfect discharge. But, to make the several discharges fairly comparable, the cable should be as free as possible on each occasion of charging. The discharge side, therefore, of the Lambert key should be tapped down a few times before recharging. The student observes that this puts the cable to earth through the galvanometer and battery key. We may now put down the charging contact of the Lambert key for a few seconds and release it, waiting one minute during which the cable leaks (discharges slowly through the insulating sheath); at the end of this time the other contact is touched down and the deflection noted. The operations are repeated at the required

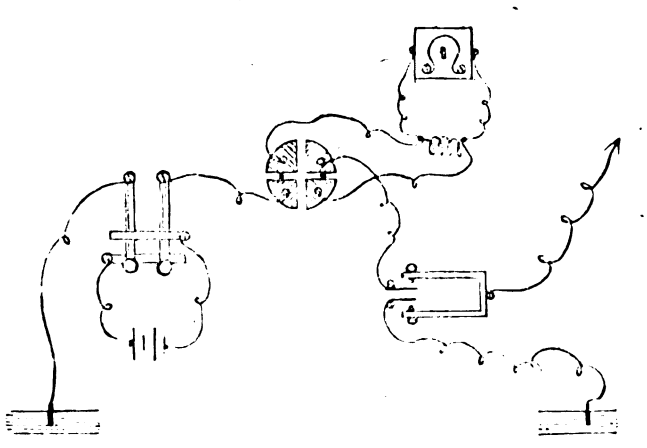

Fig. 40.—Insulation Resistance (Charge Test).

intervals; sometimes no other observations are needed. Sometimes the cable is discharged after 2, 3, 5, and 10 minutes' leakage, but the course is the same all through. The result has given us all the conditions necessary to calculate the insulation resistance by the rule above mentioned. We have the time of leakage in each observation—this is 1, 2, 3, &c., minutes, as it may be, also the capacity in microfarads by comparison of the full discharge with that of the condenser, and we have the different deflections representing full potential, and that at various intervals. We have only to work out the formula.

We are now to vary the test by the "charge" method. There is very little difference between the two tests, but the connections are slightly varied. In Fig. 40 a plan is given which might, indeed, have been used for the discharge test in place of that in Fig. 39. This way of arranging the matter would be most convenient if we wished to make it a discharge test without any alteration. The difference between the two figures is that in Fig. 39 we charge the cable separately and discharge through the galvanometer, and in Fig. 40 we both charge and discharge through it. Both tests can be taken, however, with either plan. The arrangement in No. VII. for taking capacity would also answer our purpose. It is to be observed that, for the operation now to be performed, we require a different shunt to that used just before; that is, if the same cable is being tested. This will readily appear from the consideration that the deflections in the first case are caused by a greater amount of charge than in the second. When a cable is charged for 10 or 15 seconds, it will only discharge or leak slowly through its dielectric; thus, the amount left in it after one minute is greater than the leakage, and consequently than the amount necessary to replace it when recharged. The change in shunt power must depend on several considerations, as the length of the cable, its qualities, battery power used, &c. In a case of actual practice in testing a submerged cable a shunt of one unit was used for the discharge and one of 10 units for the charge test, the deflections being about equal in both cases. Following Fig. 40, we commence, as before, by clamping down the battery key. No charge can flow as long as the Lambert key is not down; on depressing this, the cable is charged and the deflection noted. The full potential is the same whether observed by the charge or the discharge, and if we had the commutator plugs properly arranged we might charge the cable from the battery key and discharge through the galvanometer, as in the discharge test. We might then charge again, and, leaving the cable to leak for one minute, place the commutator plug in the reverse position, and after the minute by touching down the other Lambert key contact replace the amount of charge that had escaped. The deflection on the galvanometer represents this compensating quantity. The advantage of doing it in this way is that we can give the 10 seconds for the first charge, as before mentioned. The resistance is calculated so as to give the value for discharges, as previously suggested.

The earth connection to the Lambert key in Fig. 40 is for putting the cable direct to earth if needed.

In the next number we have to give other examples of this kind of test with the electrometer as well as galvanometer.

BLACKBURN'S PORTABLE TESTING BRIDGE.

When submarine telegraphy became practical, testing became a science, and the instruments used for testing purposes developed with great rapidity into scientific apparatus of very great accuracy and delicacy. Electric light work requires special apparatus, not, perhaps, of so delicate a character, because the electric currents are far more powerful than those used in telegraphy. A good deal of work has been done by "rule of thumb," the only definite object being to be on the safe side, but this must gradually give way to better and more scientific methods. The electrical engineer will have to know his instruments and familiarise himself with their use in much the same way as the civil engineer familiarises himself with the use of the chain and theodolite. Ohm's law must be the watchword of one just as square measure is of the other. Practical electrical engineers have already found the want of simple portable apparatus, and endeavours are being made to supply the want. The instrument we herewith illustrate is an example of this fact. It is a combination instrument specially designed for a certain class of work. Mr. A. B. Blackburn has designed, tested, altered, and tested, till he has produced a most compact, portable, and useful instrument. We have said this is a combination instrument, and we think justly so, in that it contains a Wheatstone bridge, galvanometer, and battery, complete, and connected up for instant use. It is, box and all, not more than about 7in. by 5in. by 1·5 in., so that it goes easily into a handbag, or even into the pocket. Its measurements are said to be fairly accurate between the limits ·005 and 2,000 ohms. Fig. 1 shows the arrangement, and is almost the exact size of the instrument, while Fig. 2 shows the connections. It will be seen from Fig. 2 that the resistance coils are placed around the circumference of a circle. Eleven coils are so arranged in series beneath the turntable. The latter carries two contact pieces, which embrace two coils. A platinum wire having double the resistance of one coil is stretched round the ege of the turntable, and joins the two

Digitized by Google

contacts. This wire is used for final adjustment, and is capable of division at any point by an index arm, this index arm carrying the battery current. In Fig. 1 the index arm is connected to two movable plugs, shown in Fig. 1 at X, and in block marked 10. One of the plugs is placed at contact X, the other in the block numbered with the number

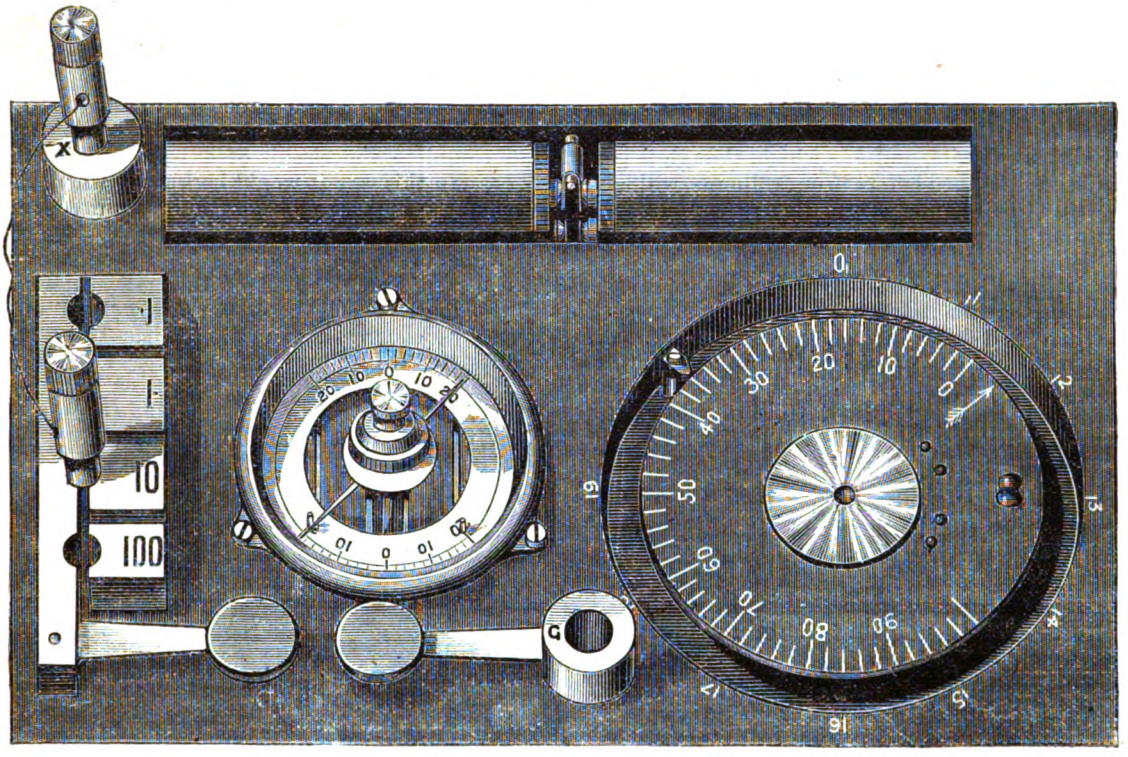

Fig. 1.—Blackburn's Testing Apparatus.

is shown at division 36 of the platinum resistance. Other coils forming another arm of the bridge are arranged in a line as shown, and have respectively the resistances ·1, 1, 10 and 100 ohms. The galvanometer is astatic, the needle being most nearly approaching the supposed resistance of the wire, carbon, &c., whose resistance is to be measured. When the instrument is used as a detector the terminal plugs are placed, one in a numbered block, and the other at G. The instru-

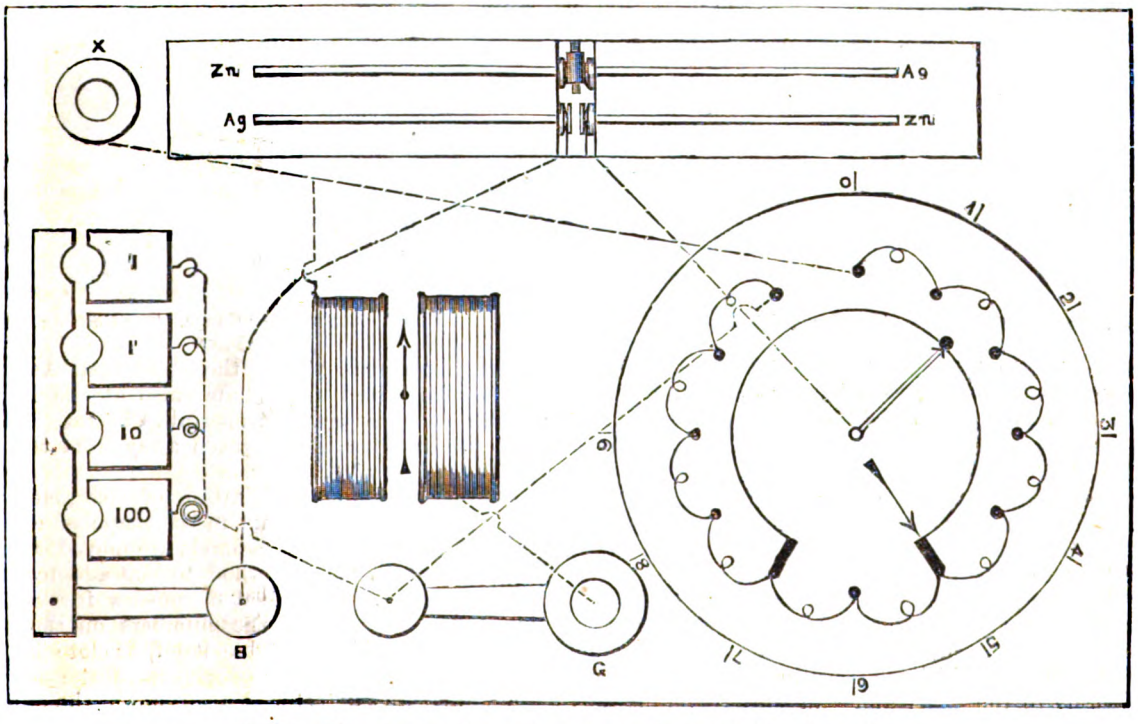

Fig. 2.—Plan showing Connections of Blackburn's Testing Apparatus.

suspended by a silk fibre. The battery consists of two chloride of silver cells joined up in series. When the instrument is used to measure resistance, the unknown resistance ment is constructed by Messrs. Clark, Muirhead and Co., who with each one issue a small pamphlet explanatory of how to use the apparatus.

THE ELECTRICAL EXHIBITIONS.

(CONTINUED FROM PAGE 392).

One of the best stands at the Crystal Palace Exhibition is, without doubt, that of Mr. JULIUS SAX, of Great Russell-street, W.C. His collection of apparatus is of a rather miscellaneous order, and ranges from water gauges to electric bells. We may begin by describing the former as the most important of all his exhibits, and one which, though it is not new, and has been described before in our columns, will admit of re-description at our hands, especially as the number and volume containing the previous description have long been out of print.

The gauge is intended primarily for use at waterworks, where the pumping station is often some distance from the reservoir, and its object is to indicate to the engineer in the pumping station the exact depth of water in the reservoir at all hours. The gauge can, however, be adapted to the lesser requirements of house cisterns. It consists of two parts, a transmitter, and receiver. The transmitter, a front view of which is shown in Fig. 1, is placed above the water the depth of which is required to be measured. To one end of the chain, which can be seen depending from the interior of the apparatus, a float is attached, and to the other a counter-weight. The chain passes over the wheel P, shown in the plan view (Fig. 2), which is geared into the pinion on spindle A. This pinion is calculated to turn round once for each inch that the float rises or falls. It is connected to the index hand by two sets of gearing, one of which is set in motion by the rising of the float, and the other by its fall, the index hand being moved forwards or backwards respectively. On the pinion A are also carried two insulated weights W, one only of which is shown in the figure. These are fitted loosely to the axle, and can only travel one way each by means of a small trigger. Supposing that the float is falling, the weight W will be carried round, and cause the contact piece C to make contact with the springs S, which will have the effect of sending a positive current over the line to the receiver, the index hand of which will indicate one inch of fall; the same action will take place for each succeeding inch through which the water may recede. Should there be a rise in the water, the other insulated weight, not shown in the illustration, will be carried round in the opposite direction to that above mentioned, and cause the contact piece Z to make contact with springs S^1, sending a negative current over the line to the receiver, which will indicate one inch of rise, and so on. Little movable contact pieces will be observed on the face of the transmitter *a* and *b*, Fig. 1. These can be set to any depth that may be required, and directly the hand makes contact with them it will complete the circuit of a bell, say in the engineer's office. In this way it would be known when the water had reached the highest or lowest limits required, or safe. A front view of the receiver is shown in Fig. 3. On starting these instruments the hand of the receiver should, of course, be set at the same figure as that of the transmitter. The working of the receiver will be better understood on reference to Fig. 4, which gives a plan view of it. The currents from the transmitter are led to the two pairs of electro-magnets shown, and, according as they are positive or negative currents, so is one or other of the wheels carrying the hand moved to the right or left by the action of the electro-magnets. This water gauge is in use at the Prudential Assurance Company's offices in Holborn, and also at the Duke of Westminster's country seat, Eaton Hall, Chester. At the former place the receiver is 150 yards away from the transmitter, and at the latter 900 yards.

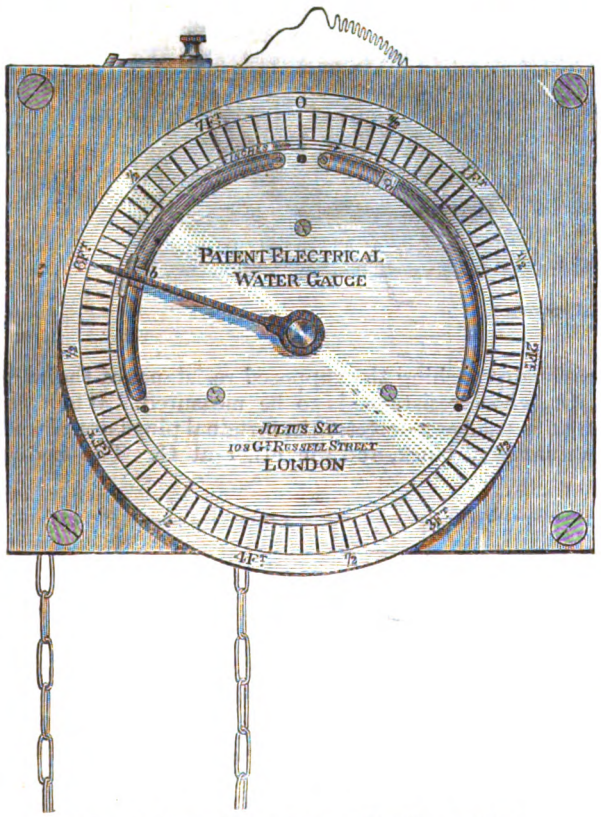

FIG. 1.—Sax's Water Gauge. The Transmitter.

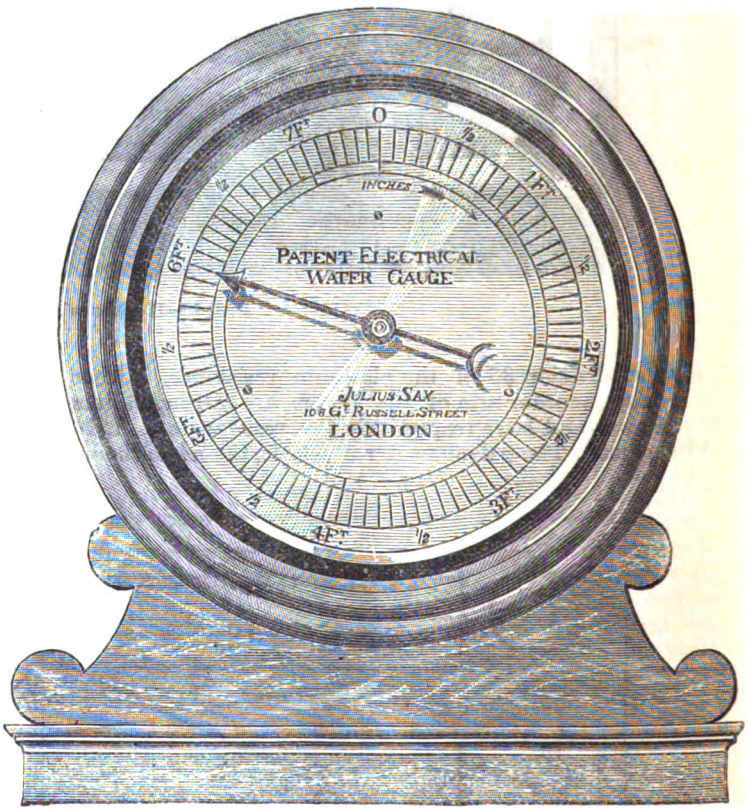

FIG. 3.—Sax's Water Gauge. The Receiver.

Another ingenious application of electricity to everyday wants is shown by Mr. Sax, in the shape of electric billiard markers. In this case the hands are moved round the dials by a somewhat similar method to that adopted in the water-gauge receiver. The contact pushes for completing the circuit and registering the numbers on the dials can be placed on the billiard table itself, or close by, in any convenient position.

A watchman's detector is also shown, the object of which is to obtain a register of the time at which any particular watchman has visited a certain part of the premises under his charge. It consists of a clock to the works of which is attached a drum, so that both revolve synchronously. Round the drum is wrapped a piece of paper divided into eight parts to represent days, and again into twenty-four to represent hours. Inkers bear against the paper, and are connected

Digitized by Google

with electro-magnets, which in turn are in circuit with contact pushes. These latter are distributed throughout the premises at the points required. Supposing the clock to be set going at 12 p.m. on Monday, the drum will begin to register from that time, and on the watchman pressing one of the contact pushes—say at 1 a.m.—the particular inker connected with that push will make an impression on the paper of the drum, and record the fact that he visited that part of the premises at that hour on that day.

In addition to the above described apparatus, a large number of electric bells are shown, as well as burglar alarms. Mr. Sax exhibits the system of bells devised by him for the Metropolitan Fire Brigade, and already fitted in several stations. It includes a switch-board in the superintendent's

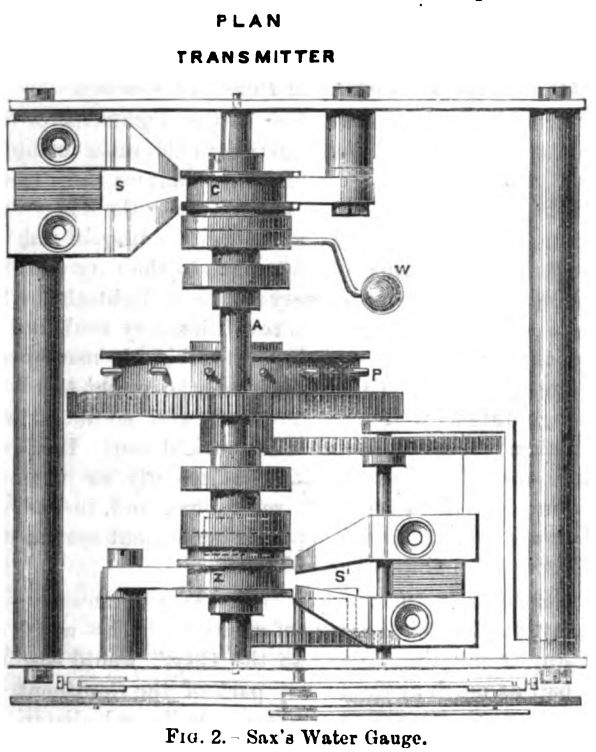

Fig. 2.—Sax's Water Gauge.

room, which enables him to cut off so many men's bells, and thus call up only those who are wanted, and also a pneumatic spring contact arrangement, the action of which is slow enough to keep the bell ringing for several seconds when once it has been set in action. Of the burglar alarms we have not much space to speak, but we may say that some of them are very ingenious. In one, which is designed for use with safes, the burglars may give the alarm in two ways, so

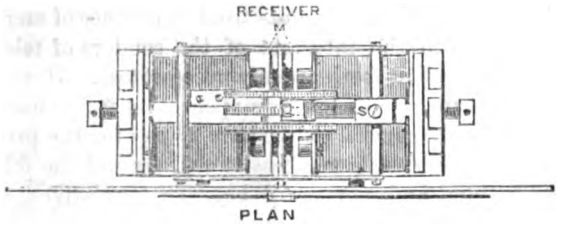

Fig. 4.—Sax's Water Gauge.

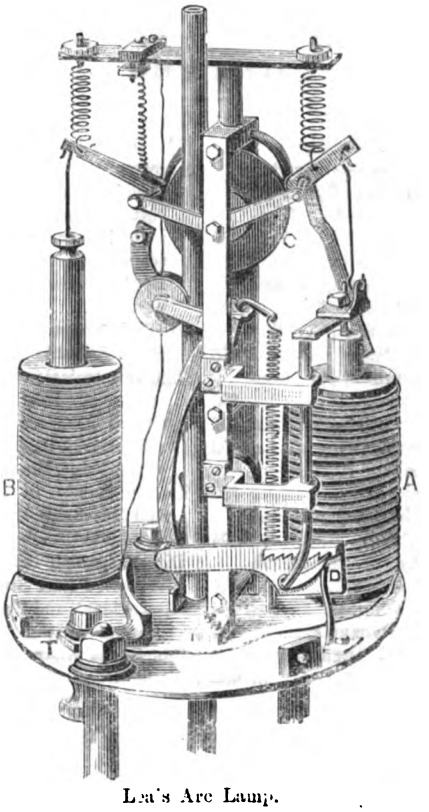
that if one alarm should be disregarded or fail to act there would be another left. Mr. Sax's exhibit, as we have said, is one of the best of its kind in the Palace, and we must also give him the credit of having been ready and his apparatus in place very much earlier than his neighbours.

The Lea Arc Lamp.

This lamp is exhibited by the Werdermann Company. The machinery occupies the position taken up by the Brush Company last year. The lamps are arranged in two circuits, each circuit having five lamps in series. The resistance of each lamp with its arc is about 2 ohms, thus giving a resistance to each circuit of about 10 ohms. The current used is 20 amperes. The E.M.F. of the machine must, therefore, be $20 \times 10 = 200$ volts. The current is supplied by two E Gramme machines, one A Gramme being used as an exciter. The action of the different parts of the lamp will be best understood by tracing the current, which enters at the positive terminal, then passes by t e uninsulated parts of the lamp to the rollers guiding the upper carbon holder and by the holder to the upper carbon, then across the arc to lower carbon, and from hence by a side rod and the thick coil A to negative terminal T. The thick coil A is wound with five layers of wire, and has a resistance of about $\frac{1}{17}$ ohm. The current through solenoid A causes the core to be drawn down; connected to this is a gripping lever, which brakes the disc C, turning it round, raising the carbon-holder and carbon, and thus striking the arc. When the core is pulled quite down, an arm fastened to the gripping lever comes into contact with a pin, thus releasing the lever, and unbraking the disc C. The action of the core of A also releases the pawl and rachet at D, allowing the spring shown close to D to act upon the



Lea's Arc Lamp.

jockey wheels, which clutch and guide the carbon-holder. The feed arrangement is as follows:—The solenoid B is wound with two sections of wire, each section having about 250 ohms resistance, one section only being in the first instance in circuit. A proportionate part of the current passes through the coil, becoming larger and larger as the arc increases in length, and hence in resistance. The action of the current draws in the core of B, to which a brake is fixed, acting on disc C. The brake acting on C slightly rotates it, and this lowers the upper carbon. Should the feed be too great the second resistance is automatically brought into circuit, thus diminishing the current through B, the pull in the core, and the action of the brake. A short circuit arrangement is made between the + and − terminals to act as a cut out. The cut out is actuated by the spring at D, which, should the carbon, for example, become too short and danger arise of burning the holders, acts as follows: The upper holder is so made that in the case cited it would fall below the highest pulley, and the spring which causes this pulley to clutch the holder pulls the pulley over and with it a long bent arm, which comes into contact with a continuation of terminal T. We have watched the feed of this lamp by the kindness of Mr. Mackie, who has charge of the exhibit at the Crystal Palace, and found it to be very constant. The inventor has, by a neat arrangement of hollow rods, made the lamp so that the lower and upper parts take asunder.

SIXPENNY TELEGRAMS.

It could hardly be by accident that the Government suffered a defeat the other evening on the question of sixpenny telegrams. The new Chancellor of the Exchequer either wished to have his hands forced, or else some influence more powerful than his own decided that they should be forced. Whichever of these two views we adopt the result is the same. The House of Commons, unless it deliberately reverses its own decision, which it rarely does, is bound to press for a reduction in the rates of telegrams within a reasonable space of time. Not so much from what he said—so the newspapers tell us—as from his manner of saying it, the Postmaster-General let it be seen that he was an advocate of sixpenny telegrams; and not so much from his manner as from his matter, perhaps, Mr. Childers betrayed that he was not. A Chancellor of the Exchequer loses nothing by being slow to part with public revenue; a Postmaster-General gains a good deal by being zealous in administrative reforms. After a friendly duel of this kind, both parties alike are decked with laurels, and the lookers-on retire much edified.

The cheers from below the gangways on both sides of the House which greeted the numbers of the division were, however, it seems to us, more exuberant than the circumstances warranted. A division, it is true, is measured quite as much by the members who abstain from voting as by the members who vote. This, as a general rule, is a legitimate way of looking at the figures; but, in the present instance, if there were but comparatively few votes recorded against Mr. Cameron's proposition there were ridiculously few in favour of it. The absentees from the Opposition lobby are quite intelligible; but that the supporters of this great innovation could only muster sixty-eight followers is a phenomena requiring explanation, and is quite inexplicable on the theory that the country is eager for the proposed change. Nobody really believes that the country is discontented with the existing rates; what is believed and known is that the newspaper interests are working to get reduced rates for their own benefit, and that there is a government in power anxious to conciliate newspaper interests. The true motive did not appear in this debate; but true motives seldom appear in debates—except occasionally in *Punch's* "essence."

Some additional force was lent to the argument for a sixpenny tariff by the recent reduction in the rates to the Continent. Its advocates were able to say that "a short message could be sent at the word rate, including the addresses, to Paris or Brussels, for 10d., while the sending of the same message from the House of Commons to the City would cost a shilling." This was a discovery such as delighteth the heart of the doctrinaire. Anomalies revolt his very soul, and he is happy only when he is squaring everything to mathematical ratio and precision. To be consistent, he ought to advocate a mileage rate as well as a word rate, and no doubt he will do so when the word-rate vein is worked out. Half-penny postage was referred to, perhaps indiscreetly, as part of the programme of the Post Office reformers; and, indeed, some of their arguments point to a purely benevolent system which shall serve the public all round gratis.

It is nothing to such people that the very message—that is to say, an English message of average length—which costs a shilling from "this House to the City," would cost more than half as much again to any part of the Continent; nor do they note the fact that, bulk for bulk and distance for distance, our inland system is as cheap as that of any other country in the world—cheaper when the difference in the value of money is taken into account. We do not expect that the man who rides a hobby will see the foolish figure he cuts, nor that those other and cleverer people who use the hobby-rider for their own purposes will tell him where he is riding to. But we have a right to demand a little more candour and sobriety on the part of our public officials. Some of the arguments used in defence of sacrificing public revenue in the interests of the senders of telegrams ought to have called forth an emphatic protest. If we are to have a minimum rate so low as sixpence, let it be clearly understood that the general public have to pay for the privilege. The general public, it is needless to say, are not the telegram sending public, and never will be. Their relatives are not always dying, and they are not prohibited sending pathetic messages because of the shilling tariff. To assert the contrary is the merest claptrap. Roughly speaking, the senders of telegrams are a class by themselves. They are a very useful class, taken as a whole, though even this can only be asserted with reservation. It may be a national advantage to subsidise this class out of the national revenue, for a subsidy it is, and nothing less; but we have seen no attempt at proving the national advantage. On the contrary, the audacious assertion is made that the charge for telegraphic communication is itself a tax and a burden upon the people. Such assertions ought not to go unchallenged, for they may prove inconvenient some day; yet the Postmaster-General himself was betrayed into language which is

Digitized by Google

capable of this interpretation—an interpretation which, pushed to its logical conclusion, would tax all non-users and non-consumers in order that a less numerous body of people may use and consume at reduced cost.

We repeat that it may be possible to prove the expediency of reducing the postal telegraph revenue and supplying the deficiency by national taxation, but as nobody condescends to argue the question on this ground we may fairly assume that the task would be a difficult one. It is even much easier to frame a resolution than to explain how it is to be carried out. "The time has arrived when the minimum charge for inland postal telegrams should be reduced to sixpence," so the House of Commons has affirmed by a vote of 68 against 50; but when we come to ways and means opinions are at variance as to the shape the the reduction shall take. The late Postmaster-General is in favour of retaining free addresses; the present occupant of the post considers them wasteful, and suggests three ways of bringing about a reduction, not one of which in all probability would receive the undivided support of a tolerably full House. The plan which he described as simplest and least costly was to continue the wasteful addresses and charge 6d. for six words, 9d. for twelve words, and 1s. (as at present) for twenty words. We do not think this would please the doctrinaires, for they would fail to see the reduction involved in sending six words for sixpence when you can now send three times as many for twelvepence; and we are sure it would encourage cypher messages to an inconvenient extent. The better plan, as every one knows who has studied the question, would be to include the addresses, and fix the maximum number of words at something like half their present average. Business people have short addresses and want long text; poor people, for whom Mr. Fawcett appears to hold a brief, have long addresses but need only a short text. Both classes would be accommodated by this plan, and the revenue would suffer least by it. But while the present superstition survives as to the prescriptive right of the English people to free addresses, it is useless to argue or to advise—one thing alone being now certain, that the senders of Press messages, their backers and their tools, will sooner or later wrest a fresh concession from the Government at the expense of the public revenue.

CORRESPONDENCE.

REIS'S TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I be allowed to comment upon the letter of Philipp Reis, and upon the remarks about it which appear in your last issue?

So far as is known, this letter is the only piece of English composition ever attempted by Reis. Of the few existing letters from his hand it is believed that all, save this, are in German. It is not surprising, therefore, that there should be, as pointed out in your article, points of obscurity in a letter written in a language which its author was so unaccustomed to employ. One blunder is so remarkable, yet so obvious, that it is surprising that it should not have been observed by the writer of your article which appears on p. 469. The word *tones* Reis, by mistake, wrote *tunes*. The second paragraph of his letter he began thus:—"*Tunes* and sounds of any kind are only brought to our conception by the condensations and rarefactions of air," &c. He obviously meant to write "*Tones* and sounds of any kind," &c., as is proved by the context; for at the end of the same paragraph we find him saying: "The smaller or greater number of oscillations made in a second gives us . . . . the idea of a higher or lower *tune*." This would be nonsense if *tune* were not evidently a slip for *tone*. Corrected to its obvious sense, the sentence is almost a *verbatim* paraphrase of a paragraph of his original memoir "On Telephony," on p. 58 of the *Journal of the Physical Society of Frankfurt-on-the-Main* for 1861.

This being so, the very slender verbal argument that Reis only intended to reproduce music—even if it were not refuted by the letter itself—falls to the ground. He clearly intended his instrument for "the reproduction of" *tones* "at any distance."

This blunder is paralleled by another which occurs in the original letter, but which, unlike the former, has been corrected in passing under the proof-reader's eye. In Reis's manuscript, where (p. 467, line 4) he is describing the arrangements of his contacts at the top of the telephone, he wrote "with the little *whole* (*a*) on the point (*a*)"; this, as now printed, runs "with the *hole a* on the point *a*." Here, again, the slip is obvious. But some one has in this case taken the liberty of correcting the blunder. There are several other mistakes of spelling (*e.g. wich* for *which*), which have been eliminated in the printing of the letter.

One other point cannot be passed by. It has been said that this letter of Reis shows that he only intended to transmit tunes and not other kinds of sounds by his telephone. The letter unquestionably shows the contrary. If Reis in his letter had said that *any sounds* could be reproduced, that would obviously have included speech; and surely he would have emphasised in some way such an important point. In one place, and one place only, did Reis emphasise by underscoring a word in his letter. What was the passage which Reis thus emphasised? *It is neither underscored, nor printed in italics in the reprint of the letter!* The passage which Reis emphasised was the following, near the end of his letter, and *in the original it stands as a paragraph, by itself*, though in the reprint it has been linked on to the preceding paragraph:—"*Any* sound will be reproduced, if strong enough to set the membrane in motion." Further comment is needless, save to inquire why the underscored word has not been emphasised in the reprint.

The suggestion that the words, "If a person sing," &c., which preface the paragraph in which Reis deals solely with what happens during singing, imply that it was not intended to transmit any other sound than singing, is so innocent a suggestion that to attempt to refute it would be cruel. It would be possible to set up an equally good argument that Reis did not intend to transmit music at all because in one place he calls the two persons who are respectively transmitting sounds and receiving them through the telephone "the correspondents."

Lastly, there is an argument (on p. 469, at the middle of the first column) concerning the "essential feature" of Reis's transmitter, which, as far as I can understand it, is to the following effect:—Reis, when describing in his letter the transmission of musical tones, spoke of the current being "opened" at every "full vibration;" therefore, he never meant to transmit anything but full vibrations, and meant the current to be opened not in proportion to the vibration, but always at all vibrations, whether full or not, just as completely as at every "full" vibration; therefore, his telephone could not speak "except by fortuitous accident." There is little to be said of an argument involving such extraordinary sequences, except that it is a very unusual and a very illogical one. Does it follow because a man says "I drink one whole bottle of wine at every full meal" that he never takes any meals but "full" ones, and that at every meal, whether full or not, he necessarily drinks one whole bottle of wine? Yet that is the logical parallel to the case. As it happens, though Reis had said it elsewhere, he did not in this his praiseworthy attempt to write an English letter, say what was to happen in the case of vibrations that were not of "full" amplitude. He never spoke of his contact arrangement as a mere "make-and-break" in the telegraphist's sense. He talked about his interrupting apparatus being for the purpose of opening and closing the circuit, which is a very different thing. And perhaps those who allege that an instrument which opens and closes the circuit cannot transmit

Digitized by Google

speech had better reflect before they repeat the fallacy that in Edison's very first patent for "speaking telegraphs" (filed July 20, 1877, No. 203,014) the first claim was for the combination with tympans of "one or more circuit-closers," which in the second claim are called "circuit-breaking connections!" And yet we do still sometimes hear that an instrument which opens and closes the circuit—patented by Edison as a *speaking* telegraph—"could not speak except by fortuitous accident!" I am inclined to think that there are some writers upon telephone questions who cannot write with logical consistency except under the same condition.—Yours, &c., SILVANUS P. THOMPSON.

Bristol, April 2, 1883.

[Our readers will be grateful to Professor Thompson for correcting the errors made by the Society of Telegraph Engineers in printing Reis's letter. Whether they will be satisfied with his interpretation of it is not for us to say. For ourselves we have only to remark that our logic—such as it is—is not in the least affected by the emendations, nor by the fact that Edison called his circuit-breaking transmitter a "speaking telegraph" in 1877.—ED. *E.*]

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to your article on the subject of Reis's telephone, and to the copy of the letter reprinted from the *Journal of the Society of Telegraph Engineers and of Electricians*, I beg to point out that the letter in the second line of the fifth paragraph of the reprint should be *c*. This will make the sketch a little more intelligible.

The word "any" commencing the sentence "any sound will be reproduced," &c., in the eighth paragraph should have been printed in italics, the word being underlined in the original letter.—Yours, &c., A. J. FROST, Librarian.

Society of Telegraph Engineers and of Electricians,
4, The Sanctuary, S.W., London, April 2, 1883.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The fact that Reis adapted a "little telegraph" with a certain code of "claps" to his telephone in order to "get understood" by his correspondent seems to point to the conclusion that articulate speech could not be transmitted.

It is to be hoped that Mr. Ladd will give fuller and more comprehensive information concerning this remarkable instrument, and so supplement the very ambiguous letter of the inventor.—Yours, &c. W. T. FARQUHAR.

ELECTRIC LIGHT COMPANIES AND THEIR EMPLOYES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There has been a good deal of criticism lately, both by the electrical world and the public at large, as to the prospects of the various electric light companies, and the way in which they are being managed; and, therefore, I venture to send you a copy of an order which one company has issued to their *employés*, and I think you will agree with me, sir, that if the officers of the said company from whom this order emanates would give their attention more earnestly and heartily to carry out the work in a practical, business-like way, that they would have something more to think of than issuing such an order as this, and trotting about in a haughty, domineering kind of way which is most repulsive both to the men and also the electricians who have charge of the various stations (for I may say that it is not *all* the officers of the company who are like this, as those in charge at stations are highly respected by the men under them); but these in charge are under those who have issued this order, and I may say, in some cases, have also a more *technical* knowledge of the work under them as well. And thus where they are requiring obeisance and respect from the men they are getting the very reverse, and also not only losing their respect but they will be losing their best hands too if this kind of policy is persisted in. The order is as follows:—"To the foreman in charge, ——— station, &c.: Instruct all your men in future when a superior officer of the company visits your station *to touch their hats*; if any man objects report him at once with a view to his immediate dismissal!!!" *(Signature.)* If *this* is what is required to make a man respectful the man had better be dismissed before the order is given, as any man would naturally tender an officer his due amount of respect if the officer knew his place and behaved with that amount of dignity which every gentlemen in such a position would do.

Hoping this will not intrude too much on your valuable space, I beg to remain, yours, &c.,

ONE OF THE WORKMEN SUBJECT TO THE ABOVE ORDER.

London, April 2, 1883.

P.S.—I may also mention that a good many of the men do not even know the said officers.

SOCIETY OF TELEGRAPH ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I regret to observe that Mr. Fahie's letter on the Society of Telegraph Engineers has passed unnoticed in your last issue. Surely it is not because the matter of which it treats has no interest for your readers, of whom many must be members of the society.

Leaving out of the question altogether the *éclat* which would redound to the society from the reading of interesting papers at its meetings, the society is a loser in a pecuniary way by the neglect of its distinguished members, of which Mr. Fahie so justly complains. Interesting papers by well known authors always carry large outside audiences, and if occasionally such audiences could be assembled at our meetings, many of their number would end by joining our ranks, and so add to our funds.

While agreeing in the main with Mr. Fahie, I must say that he is a little too unreasonable in wishing that *all* papers on electrical subjects should go to the society. The honour of contributing to the *Proceedings* of the Royal Society is what few men of science can resist; and accordingly when one has the good fortune to have a paper which the Royal Society will accept, he will never take it elsewhere, nor can we blame him.—Yours, &c., J. M.

"WHAT'S IN A NAME?"

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I quite concur with your correspondent, "Brevity," in his observations concerning the inconveniently long title of "The Society of Telegraph Engineers and of Electricians," and am of opinion that it would be most desirable, in this age of progress and rapidity, to adopt some shorter title. I would, therefore, suggest the designation, "Society of Electrical Engineers," which I think would be suitable and meet all the requirements of an institution devoted to the application and development of electricity.—Yours, &c.,

J. ANGELO FAHIE,
Memb. Soc. Tel. Engineers and of Electricians.

10, Leinster-street, Dublin, April 3, 1883.

"UNIPOLAR" DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should like to point out that the term *unipolar* as applied to Ball's new dynamo is a misnomer in more senses than one. According to your diagram on p. 406, it has four poles, one "north," one "south," two "neutral." Further, though there is only one pole-piece for each armature, the machine is not one of the class of true "unipolar" dynamos, like Siemens's "unipolar" machine and Faraday's early rotating disc machine. The term "unipolar induction," so much used by foreign writers for the induction in a sliding conductor revolving round or past one pole of a magnet, though not free from objection, is generally understood, and

Digitized by Google

its meaning accepted. Unipolar dynamos are those constructed on the principle of unipolar induction. Ball's dynamo, ingenious as it is, does not come at all within this category. If it were a unipolar dynamo it would require no so-called "commutators." It has, I perceive, two, each provided with a pair of brushes, as in all the common types of direct-current machine, from Pacinotti to Edison.—Yours, &c.,

Bristol, April 2, 1883. SILVANUS P. THOMPSON.

SAFE CURRENT THROUGH COPPER WIRE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is so clearly to the interest of all parties that reliable tables of capacities of electric lighting conductors shall be compiled, that I venture to send you for publication a copy of a report addressed to the manager of this company in November last by our consulting engineers, Messrs. Clark, Forde, and Taylor.

From reports made to us we scarcely think it would be safe to rely upon the table contained in your last supplement so far as regards large currents.—Yours, &c.,

H. CLELAND HEYWOOD, Secretary.

The Indian and Oriental Electrical Storage and Works Company (Limited), Winchester House, Old Broad-street.

(Report.)

7, Pope's Head-alley, Nov. 9, 1882.

Dear Sir: In reference to your inquiry of the 20th October as to the amount of current in amperes which could be conveyed by copper wires of different sizes, and to our letters on the subject of the 24th October and 1st November, we beg to say that we have carried out a number of experiments at Millwall, with the result of confirming our view that, up to currents of 10 amperes, or thereabouts, an allowance of 10lbs. of copper per mile for each ampere of current will be quite safe, so far as regards risk of injury to the insulating material, even though the wire be enclosed in asphalte, sand, or other such imperfect conductors of heat.

This, however, would not be true for currents very much greater than 10 amperes.

We find in such cases that, when the insulated wire is surrounded by a bad conductor of heat, there may be a rise of temperature sufficient in time to injure the insulator, though not if the insulated wire be freely exposed to radiation.

Our experiments show that the law cannot be stated so simply as "so many pounds per mile per ampere," owing to the fact that the heat developed is directly as the area of section of the wire, whilst the loss of heat by conduction only takes place in proportion to the surface of the wire. It is evident that the heat in large wires must accumulate, and the temperature rise more than in small ones.

Our experiments, in fact, show that with wires of different sizes, carrying currents of, say, one ampere for each 10lbs. of copper, the larger wires will attain a higher temperature than the smaller.

We have found experimentally that if the safe limit of rise of temperature in a wire whose weight is (w) lbs. per mile is reached when it conveys (n) amperes of current, then the same limit is attained in another wire carrying (m) amperes when its weight

$$W = w\left(\frac{m}{n}\right)\frac{4}{3}$$

Small wires will, therefore, safely carry currents having a greater relative proportion to their weight than large ones.

On the assumption that 10lbs. per mile per ampere is a safe limit up to, say, 13 B.W.G., we have calculated a table of current for several B.W.G. sizes of copper wire, which will serve practically for either solid or strand conductors.

Our letter of the 24th October dealt with the question of economy as regards interest on first cost, and we there stated in whole numbers that if we allow 10lbs. of copper per mile per ampere, one horse-power is wasted for each eight amperes of current per mile, whereas if 20lbs. of copper be allowed the waste is reduced to one horse-power for each 16 amperes per mile, and so on.

We have gone into the question of interest on first cost, assuming that the consumption of coal per indicated horse-power was 3½lbs., and its cost 40s. per ton in India. Allowing twelve hours work per day, the cost of horse-power is therefore £13 6s. 8d. per annum, and we assume the cost of the electrical horse-power to be double this, or £27 per annum, owing to the loss in conversion through the dynamo and accumulators.

The cost of insulated conductors we take from the known price of a conductor weighing 448lbs., viz., £50 or £0·112 per lb., and we assume the annual interest and renewal on first cost to be 10 per cent.

From these data we calculate that the most economical employment of insulated copper wire in India would be to use about 55lbs of copper per ampere per mile (Professor Sir Wm. Thomson gives 63lb. per mile). If we could halve the above cost of horse-power, this would reduce the weight to 40lbs. per mile; in fact, the question is one which requires calculation in each special case, the formula being

$$W = A \times 10{\cdot}75\sqrt{H}$$

W being the total weight in lbs. per mile,
A the current in amperes,
H the cost per annum of the horse-power.

From these considerations it is obviously economical to use large conductors, and it is even more economical to use high electromotive force, since you can by this means transmit the same amount of work with fewer amperes of current.—Yours, &c.,

(Signed) Clark, Forde, and Taylor.

T. M. Collet, Esq.,
Indian and Oriental Electrical Storage and Works Company (Limited).

LITERATURE.

Physics in Pictures. The principal natural phenomena and appliances described and illustrated by thirty coloured plates, for ocular instruction in schools and families. With explanatory text, prepared by T. ECKARDT, and translated by A. H. KEANE, M.A.I. [Edward Stanford. London: 1882.]

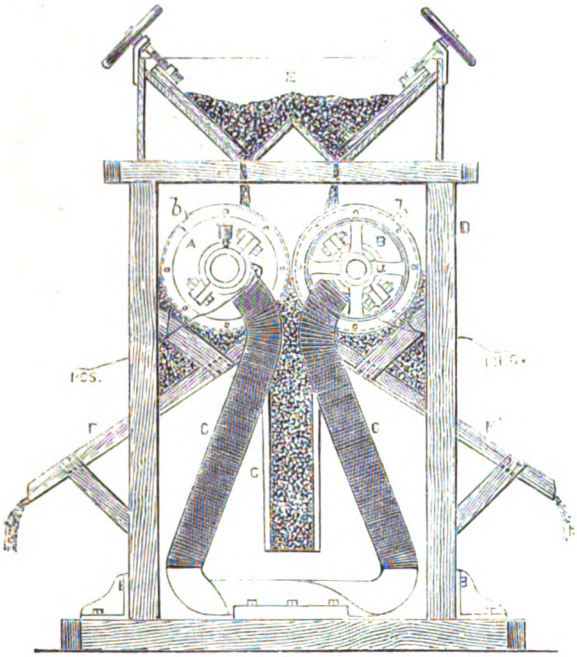
Those who have any interest in the education of children will welcome this book as an aid to instruction. The proficient in science prefers possibly a diagram to a coloured picture, but a child prefers the picture to the diagram—pores over the picture, knows every square inch of surface, and so carries the picture in his mind as to illustrate any similar phenomena he comes across that is depicted by it. We have here some thirty sheets of brightly-coloured pictures, which appeal to the eye. In a few instances the apparatus depicted is old fashioned, but as a rule the lessons that it is desired should be learned are well illustrated. The fire engine depicted may be of a type a little out of date, but the principle is the same as in the engine of the most recent type. Explanatory letterpress accompanies these pictures, but we should imagine that the parent or teacher had better depend upon his or her own knowledge of the subject than upon letterpress. The child learner has an inconvenient habit of asking for information that is not supplied by letterpress, and is highly delighted if the teacher will just answer questions, and not attempt to go through a set description. We have tried the effect of putting this book into the hands of children, and we are quite satisfied that it is of very great use. Try to explain "centre of gravity" to a boy of eight without apparatus or diagram, and note the result. Now try again, but aiding explanation with experiment; put the boy on one leg, put him upright against the wall, heels and shoulders touching the wall; let him have a first attempt to stand on his head, and he will soon realise the why and wherefore of the positions as shown in Plate I. of this work. A few ideas really grasped by the aid of experiments will expand the mind sufficiently to enable it to grasp

Digitized by Google

many of the principles illustrated in this book. The teacher must be a living teacher, having a mind of his own, able to take advantage of a gleam of light shown by the questioner, and then he will appreciate the aid of such a book as the one Mr. Stanford now presents to us. We shall not enter into a detailed criticism of each sheet of pictures, but accept the broad fact that many fundamental scientific principles are fairly illustrated. The scale of the pictures is large, and thus the parts are easily seen, and the colouring is clear.

THE BUCHANAN MAGNETIC SEPARATOR.

Among the many recent applications of electricity to the arts, one of the most interesting to those engaged in mining and metallurgy is that of concentrating ores. Though repeatedly attempted, particularly for magnetic iron ores, by the use of permanent magnets, it was not until the perfection of dynamo-electric machines permitted the economical generation of electric currents that any work worthy of serious attention was done. Naturally, the first field in which any effort was made was in the dressing of magnetic iron



The Buchanan Separator.

ores, and sands containing that ore, and in this direction the greatest progress has been made in this country. It may be of interest, however, here to recall the fact that, at a number of places abroad, magnetic separation has been extended to other classes of ores, notably close mixture of spathic iron ore, or iron pyrites and blende, previously roasted, as it is possible that by this remain similar ores, now useless, may be made available here. The principal field of magnetic separation will, however, always remain the dressing of magnetic iron, sands, and ores. In the case of the former, drying in a suitable revolving cylinder is resorted to, while with the latter class of material a system of crushing, pulverising, and sizing is necessary. Mr. C. G. Buchanan, of this city, the inventor of the machine we are about to describe, has shown us a sketch of a mill for this purpose, in which he has, by suitable exhaust arrangements, provided for the removal of the dust made during the crushing and screening, which would prove objectionable in the later separation. The principal market for fine magnetic ore, obtained by this system of dressing, is, of course, for forge fires and puddling furnace fix, the quantity which could be used in blast furnaces being limited by the inconvenience which raw material of such fineness would entail in the working of the furnace.

The Buchanan magnetic separator, which we illustrate this week, has been at work for upwards of two years on sands, at Block Island, and possesses features of special interest. A and B represent the two cast-iron rolls, provided with heavy wrought-iron shafts or journals. In section, these rolls have an oval core, so that the surface of the rolls is uniformly magnetic. The distance between the surface of the two rolls is two inches. C C represent the iron standards supporting the rolls, and having journals in which they revolve. The rolls are provided with brass collars, *b b'*, intended to prevent the ore from dropping outside of them. D represents the wooden frame to which the stands are bolted, and it also supports the hopper E, and the chutes F and G. The standards C are first insulated and then closely wound with heavy insulated copper wire, and the two ends of the wire are connected with the poles of a dynamo machine. It is evident that, if a strong current of electricity is passed through the wires, the standards C will become powerful electro-magnets, and that, if they are properly wound, each end of the same standard will be of opposite polarity, as indicated by the wires marked positive and negative. It is also evident that the rolls will be charged by induction, and that one roll will be of north polarity, and the other south. The peculiarity of this arrangement is, that a powerful magnetic field is formed between the rolls, and they are capable, while charged, of holding a weight of 500lb. or 600lb., if it is placed between them, while on their opposite side they are practically non-magnetic, and will not hold a tack.

The variations needed in dressing ores of different grades and sizes are controlled by regulating the power of the current of the dynamo-electric machine. The latter is of a special pattern, producing a current of a low electromotive force, the wire being heavier, and larger electro-magnets being chosen. It is built by the well-known Weston Electric Light Company.

The operation of the machine is as follows: The rolls are rotated towards each other, at a circumference speed of 150ft. per minute, and the hoppers opened so that the ore falls upon the top of the rolls. In passing over the rolls it is carried through the magnetic field, and all that is magnetic is attracted and attached to the faces of the two rolls, and carried around by them to a point where they lose their magnetic effect, and the ore falls into the chutes F F. The rock, being acted upon by gravity alone, falls directly into the chute G, and a nearly perfect separation is thus effected.

The Union Foundry Company, of Rockaway, N.J., which builds these machines for Mr. C. G. Buchanan, the inventor, manufactures three sizes, the largest having rolls 24in. in diameter and 36in. long, with a capacity of treating 100 tons of ore per day, and larger quantities of sand. The range of sizes seems to be considerable. We are informed that ores as fine as from 40 to 60 mesh, and as coarse as from 8 to 10 mesh have been treated successfully.—*Engineering and Mining Journal*, New York.

ON THE INFLUENCE OF THE CHEMICAL NATURE AND DENSITY OF ABSORBED GASES UPON THE ELECTRICAL CONDUCTIVITY OF CARBON.

(Preliminary Note.)

BY ALFRED W. SOWARD AND I. PROBERT.

It has long been known that carbon has the power of condensing gases within its pores. De Saussure, who first investigated this absorptive power, found that at 12deg. C. and under 724 mm. pressure a piece of boxwood charcoal, which had been previously heated to redness and then cooled under mercury in order to remove air from its pores, would absorb 90 times its own bulk of ammonia, 35 of carbon dioxide, 9·25 of oxygen, 6·50 of nitrogen, and 1·25 of hydrogen. Hunter, who has examined the subject more recently (*Phil. Mag.* [4], XXV., 364; XXIX., 116) has found that a piece of porous (cocoa-nut) charcoal at 0 deg. C. and 760 mm. pressure, would absorb 171·7 times its own bulk of ammonia, 67·7 of carbon dioxide, 17·9 of oxygen, 15·2 of nitrogen, and 4·4 of hydrogen. From these figures it will

Digitized by Google

be seen that the more readily condensable the gas the larger is the quantity absorbed, and the experiments of Malsen (*Comptes Rendus*, LXXVI., 81, 92), seem to prove that some gases at least are actually reduced to the liquid state within the pores of the carbon.

Graham discovered that certain metals have the power of absorbing or "occluding" many times their own bulk of hydrogen; palladium, for instance, at the ordinary temperature absorbs 376 volumes of that gas. This absorption was found to be accompanied by an increase in the bulk of the metal, and a decrease in its electrical conductivity.

Although the analogy between the occlusion of hydrogen by metals (accompanied in all probability with the formation of definite alloys) and the absorption of gases by carbon (in non-atomic proportions) is not perfect, there is still sufficient resemblance for the question to be suggested whether the electrical conductivity of carbon may not be affected by the absorption and liquefaction of large quantities of gas in much the same way as that of palladium is affected by the occlusion of large quantities of hydrogen.

We have during the past year been conducting a series of experiments having for their object the preparation of an extremely dense and non-porous carbon for electrical purposes. In the course of these experiments we have had the opportunity of measuring the electrical conductivity of samples of carbon in atmospheres of different gases at various pressures; and we have found that the conductivity of a piece of porous carbon is not a constant for a given temperature, but varies with the nature of the gas surrounding it (and consequently absorbed in its pores), and also with the pressure of that gas. The conductivity of a piece of porous carbon would not be the same at the summit of Ben Nevis as at its foot; it would not be the same in the air of Hyde Park as in the fire-damp laden air taken from a coal mine. This variation of the conductivity of carbon with variation of pressure we have found to be a very convenient test of porosity.

It has been said that there is an essential difference between the resistance of a pile of carbon powder and the resistance of a block of carbon, that the first resistance is not a true resistance, as it is not constant for currents of different strengths; the air spaces between the particles of carbon powder are stated to be the cause of this. But we venture to think that the heap of carbon powder is but an extreme case of porosity, and that it would be possible to prepare a series of carbons which should range in porosity (and in properties dependent upon porosity) from the dense carbon whose resistance is practically constant for all pressures, through many intermediate stages, without break of continuity, to the heap of carbon powder whose porosity is a maximum.

Experiments are in contemplation to determine quantitatively the variation of the conductivity of different varieties of carbon with variation of the chemical nature of the absorbed gas and with variation of its density.

HISTORIC NOTES ON THE TELEPHONE.

BY J. J. FAHIE, MEMB. SOC. TEL. ENG. AND ELEC.

Seeing of late a good deal about the telephone in the pages of *The Electrician*, it has occurred to me that a few facts on its early history would not be uninteresting. I therefore give below such notes as I have been able to collect in the course of my researches in dusty tomes. Many of the references will, doubtless, be familiar to those of your readers who have studied the telephone, but a few will, I think, be regarded as "facts not generally known."

Passing over the claim of the Chinese to the invention of the telephone as "not proven," we come to the year 1837, when Professor Page, of Salem, Massachusetts, observed the sound that was produced in iron by magnetisation and demagnetisation. This phenomenon was explained by De la Rive, of Geneva, in 1843, who showed that it was caused by the slight elongation of the iron which accompanies the act of magnetisation, a fact discovered by Dr. Joule in 1842. Page's receiver consisted of a bar of iron surrounded by a coil of wire. These bars were of considerable dimensions, some as much as 3ft. long and 1in. to 2in. diameter. With powerful currents the sound emitted was heard as a click, and when these clicks were made to follow each other with sufficient rapidity a certain note was produced whose quality depended, of course, on the number of clicks per second. By an automatic make and break arrangement as a transmitter, Page obtained sounds sufficiently loud to be heard at a considerable distance.

The next step in the evolution of the telephone is claimed for Mr. Edward Farrar, of Keene, New Hampshire, U.S. His proposal was to transmit sounds of different pitches by the vibration of an armature of an electro-magnet. The *modus operandi* is thus described by the author himself in a letter written in 1851, and which his friend Mr. Brackett published in *The Scientific American* in 1879:—"Each reed of a melodeon is furnished with a small metallic point, which, while the reed is at rest, approaches near to the surface of mercury in a very small cup underneath the reed, into which the point dips when set in motion. The reeds are connected with one pole of a battery, and the cups with the other. The current is broken with each vibration of the reed. At the remote end of the wire is a temporary magnet, with an armature fixed upon a spring in near proximity to the magnet, and which is affected as a reed at the other end of the line is set in motion. The effect is that the armature vibrates with the reed set in motion, and, as the pitch of a sound depends on the rapidity of vibration, it will be the same in the reed and armature. A tune on the instrument will, therefore, produce a tune on the armature. What may appear somewhat strange, several different tones may be heard when chords are struck upon the instrument. The object of my inquiry was this: If the current power could be varied by some slight variation of a vibrator to be affected by the atmosphere as the tympanum of the ear is, the supposition is that the sounds of the voice might be reproduced by the means stated above."

Professor Dolbear says, in his paper "On the Development of a New Telephonic System," read before the Society of Telegraph Engineers and of Electricians, March 23, 1882:—"Though Farrar spent some time in attempting to solve the problem of the transmission of speech by electricity, he did not succeed. He had some written communication with one of the foremost men of science in New England at that time (1851) as to whether such a device could be made, and as to its practicability, but the reply he received was so discouraging that he abandoned the attempt."

The next attempt was a musical telephone again, the invention of a M. Paterna, of Prague, about 1852. It was a keyed instrument, which, by means of an electro-magnet, set a small iron plate or armature in vibration as soon as the hand left the key. Each key gave a different note, and a similar instrument at a considerable distance was caused, by a connecting wire, to give out the same tones. This apparatus is described in Dingler's *Polytechnisches Journal* for 1852, also in Böttger's *Polytechnisches Notizblatt* for 1853.

In the *Builder* for May 5, 1855, there will be found a reference to the submarine cable then just laid between Varna and Balaclava, in the course of which occurs the following remarkable passage:—"It would not now be difficult, by some little further novelty of invention, to cause the reverberation of the very cannons themselves, as it were, to be transmitted, in the shape of electric vibration, through the 3,000 miles of intervening wire, and heard, in still continuous vibrations, finally communicated to some acoustic apparatus in the British Houses of Parliament! Such is the close co-relationship of forces, that this is literally perfectly possible; and, although it would not be precisely the sound of the cannons which our legislators would hear, it would actually be the vibratory reverberations of that very sound itself, for all sounds are vibratory forces, which reverberate into the electric interiors of material substances; and some recent experiments have curiously illustrated this very point in physical science."

Our next reference is of a similar kind to the last, a mere expression of opinion, on theoretical grounds, of the possibility of transmitting the human voice to a distance by the agency of electricity. *Apropos* of this M. le Comte du Moncel (*Exposé des Applications de l'Électricité*, Paris, 1857) has the following, which to-day reads strangely enough:—"I did not wish to bring forward in the chapter on the electric telegraph a fantastic conception of a certain M. C. Boursel, who believes that it will be possible to transmit speech electrically, because it might have been asked why I had classed among so many remarkable inventions an idea that is not more than a dream?" "The idea that is not more than a dream" is thus described in the same work:—"Imagine that one speaks near a mobile plate, flexible enough not to lose any of the vibrations produced by the voice; that this plate establishes and interrupts successively the communication with a battery. You may be able to have at a distance another plate which would execute at the same time the same vibrations. It is true that the intensity of the sounds produced would be variable at the point of departure where the plate is vibrated by the voice, and constant at the point of arrival,

Digitized by Google

where it is vibrated by electricity. But it is demonstrable that this would not alter the sounds."

The next note is a mere newspaper paragraph, and is to the following effect:—"The Abbé Laborde, in a paper read before the French Academy, and printed in the last number of the *Comptes Rendus*, showed how vibrations may be transmitted and reproduced at a distance by electricity—April 14, 1860." Against the same name in Ronalds' catalogue we find the following entry:—"Note on a New Electric Telegraph, whose indications are given by means of sound" (*Comptes Rendus*, XXI., 526, Paris, 1845).

The experiments of Professors Wheatstone and Helmholtz, in which were employed tuning-forks in connection with electro-magnets, are so well known as to need only the briefest mention here; we will therefore pass on to a consideration of the labours of Reis, who comes next in the order of time. As the back numbers of *The Electrician* contain all that can be said about Reis's *latest* improvements in telephony, his *earlier* labours, being not so well known, and not less interesting, will solely occupy us here.

According to a letter which Dr. Messel, a former pupil of Reis, addressed in December, 1877, to Professor Barrett, of Dublin, Reis's first experiments date as far back as 1852. But at that time they ended in failure, and were not resumed until 1860, about which time the first published account of them appeared in a daily paper of Frankfort-on-Main.

"The first instrument," says Dr. Messel, "was of a most primitive nature. A bung of a beer-barrel had a conical orifice cut through it, the smaller end being closed with the skin of a German sausage, which did service as a membrane. To this was fixed, with a drop of sealing-wax, a little strip of platinum (or a platinum wire) representing the hammer of the ear, and which closed or opened the circuit precisely as in the instruments of a later date. The receiving instrument was a knitting needle, surrounded with a coil of wire, and placed on a violin to serve as a sounding board. Some idea of the roughness of the main parts of the first telephone can thus be formed. When first exhibited at Frankfort it astonished every one quite as much as the more perfect instruments of Bell now do. The apparatus here described has now passed into the hands of the Telegraph Department of the German Government."

Reis gave his first public lecture in October, 1861, before the Physical Society of Frankfort-on-Main, an account of which is published in the annual report of that society for the year 1861. It is entitled "Telephony by Means of Electric Currents." He describes the way in which he was led, from the study of the human ear, and the manner in which it receives the impression of vibratory movements, to the construction of an instrument similar in principle, which should reproduce musical tones and even the sound of the voice in speaking.

A cubical wooden block was pierced by a conical opening, the smaller end of which was covered by a thin skin, and to the centre of this skin was fastened a narrow strip of platinum, joined to one end of a small voltaic battery. Close to, but not touching this strip, was a wire connected to the distant receiver, returning thence to the other pole of the battery. His receiver was still a simple knitting needle surrounded with a coil of wire, and supported upon a resonant box. Speaking into the broad end of the cone, the membrane was thrown into vibration, and intermittent currents were sent to the distant receiver. Here the rapid magnetisation and demagnetisation of the iron core by the interrupted current gave rise to a series of sounds. Here are his own words as to the performance of this early form of instrument:—"I was able to make melodies audible to a numerous audience at the Physical Society of Frankfort-on-Main. Melodies were sung, not loudly, into my apparatus in a hospital about three hundred feet away from the listeners, care being taken that no sound could be heard by direct means, or by conduction along the wires. The sounds of various musical instruments were also clearly reproduced, as the clarionet, horn, organ-pipe, and even harmonium or piano, when the transmitter was placed on their sound-boards, provided the tones were within a compass of about three octaves—F to f''' So far, articulation has not been reproduced equally well. Consonants, however, were in general pretty clearly heard, but not the vowels. The sound, in all cases, is of course much feebler than in the originating instrument."

Subsequently Reis achieved greater success in reproducing articulation. In a report of Reis's telephone by a M. Legat, Inspector of Telegraphs in Cassel, &c., published in 1862,* the following sentence occurs:—"Melodies can be reproduced with astonishing certainty, whilst single words, in reading, speaking, &c., were less distinct, although the peculiar modulations of the voice in speaking, calling, interrogation, surprise, or command were clearly marked." The instrument described in this report is somewhat different from the earlier form. The diaphragm was a collodion film, and the contact-breaker behind it was lighter, and constructed in the form of an S-shaped lever, the longer arm of which was in contact with the membrane, while the shorter made and broke the circuit. There was no metal disc on the membrane, but the circuit was completed by means of the arm on which the lever delicately moved. The receiver, moreover, was a small horse-shoe electro-magnet, fixed horizontally to a sounding board. The rapid isochronous movement of a light keeper, adjusted by a spring before the poles of the magnet, reproduced the original sounds.

Still more success as regards articulation appears to have been achieved a little later; for, in a paper on Reis's improved telephone, published in Germany in 1863,* it is stated:—"Particularly distinct was the reproduction of the scale. The experimenters could even communicate to each other words; only such, however, as they had already heard frequently." In confirmation of this may be added the following extract from a recent letter received from Dr. Messel:—"There is not a shadow of a doubt about Reis having actually achieved imperfect articulation. I personally recollect this very distinctly, and could find you plenty of ear-witnesses to the same fact."

Two or three years later, in 1865, a skilful instrument maker in Dublin, Mr. Yeates, showed to the Philosophical Society in that city a modification of Reis's telephone, wherein a near, though accidental, approach was made to the true principle of an articulating telephone—namely, the employment of a continuous electric current of varying strength. This was obtained, though the primary object was different, by putting a drop of water or a fragment of moistened paper between the metal disc on the membrane and the adjacent platinum point which completed the electric circuit. Articulation of an imperfect kind was thus obtained. Unaware of Reis's improvements, Mr. Yeates also employed a simple and a very effective form of electro-magnetic receiver, which deserves to be more widely known. Upon a light sounding-box a little electro-magnet is supported by a brass pillar. A light iron keeper is fastened at one end by a flat steel spring to a wooden bridge, which can be raised and lowered by a screw. The distance of the keeper from the poles of the magnet can thus be adjusted with great nicety—a point of some importance. The ends of the wire round the coils are connected with binding-screws, to which are joined the line wire leading to the distant receiver and the return wire. With this little instrument an audience of a thousand people can easily hear musical airs sung into the transmitter, which may be many miles away.

In conclusion of this portion of our subject we have to acknowledge our obligations to a paper on the Electric Telephones of Reis and Bell, contributed some years ago by Professor Barrett to *Good Words*.

About the same time that Yeates, in Dublin, was introducing improvements into the Reis telephone (one of which, the water contact, would almost entitle him to a share in the discovery of the undulatory principle since appropriated by Bell) an Italian mechanic, named Manzetti, appears to have designed an instrument for the same end. Unfortunately, we have no more information respecting this invention than is contained in the following extract from the *Petit Journal* of Paris, November 22, 1865:—"A new discovery, which will produce immense results in its application to the arts and industries, has recently been added to the numerous wonders of this century; it is the transmission of the sounds of the voice by telegraph. The author of this invention is Signor Manzetti, of Aosta, who is also the inventor of a celebrated automaton. He transmits words with the ordinary telegraph wire, and with an apparatus more simple than that which at present serves for despatches. Henceforth, two merchants may communicate instantaneously their business affairs between London and Calcutta, informing each other of their speculations, agreements, &c. A number of successful experiments have been made, which confirm the practicability of this invention. It also transmits musical notes, &c."

Our next note refers to a claim which is equally vague as the last, and rests upon still more slender foundations, to wit, the *ex post facto* statements of the claimant himself. In saying this we do not by any means wish to insinuate that these statements are unworthy of credence. We give the paragraph as we found it in the *Journal of the Telegraph*, for May, 1877, leaving it to our readers to draw their own conclusions:—"There is another claimant in the field for the honour of inventing the telephone. Dr. James Davis, of Salisbury, N.C., writes to the *Raleigh Observer*, stating that his 'phonetic telegraph,' invented ten years ago, anticipated the discoveries of Messrs. Bell, Gray, and others. Dr. Davis says that he made pen-and-ink drawings at

that time, fully illustrating his invention, and that he described his apparatus to persons whom he names. He declares that his device covered the changing of air vibrations into those of electricity, and restoring the air waves after transmission; that his apparatus was more perfect than that which the present inventors exhibit, and that it could write or register the sounds in a distinct language."

Our last quotation is from a source where one would least expect to find it, viz., in the post-prandial oration of a Minister Plenipotentiary! At a grand banquet given to Professor Morse in December, 1868, Sir Edward Thornton, then our Minister at Washington, said, in the course of his response to the toast of his Sovereign, "Should I have the good fortune to live to the age of the venerable professor, I hope to see some such improvements as will enable us to carry on *vivâ voce* conversation by means of the cable. We shall then have merchants on this side of the water discussing their affairs with those of the other at so much a minute. We shall hear, perchance, of some love-stricken youth of London or Paris whispering soft nothings along the cable to one of those bewitching syrens of New York at so much an hour, she tempting him all the while to throw himself into the gulf which separates them. We shall have statesmen, aye, and in those days of progress, even stateswomen, discussing international questions at so much a conference, and we poor diplomatists shall run a very good chance of being exploded altogether."

Considering the occasion, many people would, perhaps, pass by these sentiments with a sneer, characterising them as mere fantastic conceptions, as ideas that are not more than a dream, if, indeed, they would limit themselves to expressions so mild; but we, having the sad fate of the Comte du Moncel before our eyes, and being still on the right side of forty, hesitate to adopt this course. The British Minister, of course, spoke in jest, but we, seeing that more unlikely things have come to pass, may echo his sentiments in earnest.

THE TRANSMISSION OF POWER BY MEANS OF ELECTRICITY.*

(CONCLUDED FROM PAGE 479.)

As a supplement to the foregoing figures, I have the honour of communicating the results of the second series of experiments, which were made on the 18th February at the Northern Railway workshops, with M. Marcel Deprez's instruments and the same installation. Nothing had been changed as regarded the apparatus, and it was proposed merely to again ascertain the work done, giving the shaft of the generator a speed of about 900 revolutions per minute—that is an increase of one-half on that of the trials on the 11th February. The observations were carried out as before, except that the electrical readings were obtained with Deprez galvanometers under the control of my *confrère*, M. Cornu, who kindly undertook this duty. Five experiments only were made under ordinary working conditions, the object of the first being the determination of the work expended in working the generator idle only. The eighth must be put aside, as, the paper having broken, the dynamometer pencil could give no indications, and the seventh must be pointed out as less accurate than the others as far as the motive power is concerned.

The data collected were as follows:—

The Measurement of the Current.—The indications of the current galvanometer in the circuit of the dynamos and the telegraph wire oscillated during the whole of the experiments between 10·5 divisions and 11 divisions, or an average of 10·75 divisions, which correspond, according to the constant of the instrument as given by M. Deprez (1 div. = ·25 ampere), to a nearly constant current of 2·687 amperes. This will be found to be in accordance with the other figures.

The Measurement of the Difference of Potential at the Terminals of the Machines.—The current in a shunt circuit taken from the terminals of each machine, and composed of a known resistance, 50,000 or 30,000 ohms successively, was measured by a sensitive galvanometer having a resistance of 56 ohms. (This figure was given by M. Deprez.) The constant of the instrument, 1 div. = $\frac{1}{220}$ ampere, enabled us to calculate the electromotive force in volts for each observation, by means of either of the formulas,

$$E = \frac{n}{220}(50{,}056), \text{ or, } E = \frac{n^1}{220}(30{,}056).$$

* Report on the Results of the Experiments made by M. Deprez in the workshops of the Northern (of France) Railway, presented to the Paris Academy of Science by M. Tresca.

Below (Table III.) are given the direct readings obtained:—

TABLE III.—Readings of the Galvanometer.

No. of the Experiment.	Zero of the Galvanometer.	Resistances added. 50 000 ohms. Generator.	50 000 ohms. Receiver.	30 000 ohms. Generator.	30 000 ohms. Receiver.
VI.	− 1·25	+ 6·50	− 7·50	+ 11·75	− 11·60
VII.	− 1·50	+ 5·00	− 6·60	+ 9·60	− 10·00
IX.	− 1·55	+ 7·50	− 8·90	+ 13·80	− 13·80
X.	− 1·55	+ 7·75	− 8·95	+ 13·90	− 13·90

The values of the deflections, n and n^1, which result by means of addition for the two machines respectively, should for each of them show a constant relation for $n : n^1$, and the verifications of this relation serve to show that the constants of the instruments remained very steady during the experiments. By introducing the values of n and n^1, deduced in this way, into the above equations, which give the corresponding values of E, the electromotive force between the poles of each of the machines can readily be obtained.

The measurements having given almost identical results as regards the E.M.F. at each experiment, the averages given in Table IV. may be trusted:—

Measurement of Mechanical Work.—The same dynamometer and the same brake which were employed on the 11th February were again used. The results of the four complete experiments are given in Table V., which is similar in form to those already given. The relation between the speeds of the receiver and generator was in this case 395 : 814 = ·743, whereas in the experiments made on the 11th February it rose to ·620 only. Table V. shows at a glance the losses at each point of the circuit. I shall endeavour to offer some explanations which the figures in the table seem to call for.

1st. The figures for the work in experiment VII. are rather uncertain, although the mean ordinate of the diagram was made over a length of about two metres.

2nd. The work recorded when running idle was in this case much greater than in the first series of experiments; the belts had certainly been tightened up, and were too taut. Each revolution of the dynamometer corresponded to a work of ·0172 horse-power, whilst in the first series we found it to be ·004 horse-power. However this may be, the 2·196 horse-power (see Table VI.) comprised the friction of belts and resistances, counter shafting, &c. If, indeed, any magnetisation existed or was produced when running idle, this work would also have been registered. It would be necessary in all cases occurring in practice to look from the speed of the motor shaft to that of the generator, and in almost all cases it will be found that the resistances are of the same class. As regards the electric work, however, and the losses which it sustains, it is necessary to make a separate calculation for this loss of transmission.

3rd. This deduction having been made from the motive power, the power at disposal is reduced to 8·193 horse-power over 10·389, or to ·789 of its primitive value as measured on the dynamometer.

4th. The heat which would be produced on the expenditure of this motive power by the passage of the current in the generating machine, the resistance of which when idle and cold was 56 ohms, represents a fall in the power equal to ·549 horse-power, common to all the experiments.

5th. Experiment proves that there is another and supplementary fall in power which occurs between that absorbed by the generator and that lost in the circuit by the current; this loss reaches on an average ·844 horse-power, and represents all that has not been reckoned in calculating the heat developed in the generator. Is the resistance of this generator greater when

working with a closed or interrupted circuit? Within what limits do the brushes loose the current? What is the loss through sparking? Are opposing currents produced which increase the resistances? Such, and such as these, are the questions which we only glance at generally, leaving their solution for further study.

6th. Did the current made to traverse the telegraph wire which connected the two stations invariably represent only 6·799 horse-power, that is to say ·654 of the motive power, or ·829 of the power at disposal on the shaft of the generating machine?

7th. In traversing the telegraph wire of 17 kilometres in length and of 160 ohms resistance, the energy transformed into heat should represent $\frac{\overline{2\,687}^2 \times 160}{g}$ kilogrammetres, or 1·570 horse-power; we found the average difference between its exit from the generator and arrival at the receiver to be 1·373 horse-power only. Having regard to the small variations in the current, which were not measured during the course of the experiments, these two values may be taken as identical.

8th. The observations made at the motor showed that the current represented there but 5·424 horse-power, that is ·522 of the original motive power, or ·662 of the mechanical power at disposal at the shaft of the generator.

9th. The resistance of the receiver, taken as 83 ohms when idle, corresponds to a transformation of ·814 h.-p. of energy into heat, which is indicated in the 9th entry in Table VI.

10th. But this does not nearly correspond with the difference between the motive power of the current on entering the receiver and the work expended in friction on the brake attached to its shaft. The difference, which amounts to 1·309 h.-p., should be attributed to the causes already enumerated in paragraph 5, and to which must be added the passive resistance of the shaft of the receiver, no direct value for which was obtained as in the case of the generator. This loss would seem to have notably increased during the high electromotive forces generated in the second series of experiments, and a portion of this increase must without doubt be attributed to sparking.

11th. Finally, we come to the work measured at the brake, the average of which was only 3·304 h.-p., that is ·318 of the motive power, or ·403 of the power at disposal at the shaft of the generator. The work expended in the shape of heat, and necessarily lost, may be added as follows :—

	H.-P.
In the generator	·549
In the intermediate circuit	1·373
In the receiver	·814
Total	2·736

This is equal to ·263 of the mechanical power expended, or ·334 of the power at disposal at the shaft of the generator.

On the other hand, the losses which cannot be calculated reached

	H.-P.
In the generator	·844
In the receiver	1·309
Total	2·153

Which form ·207 of the total power, or ·263 of the mechanical power at disposal at the shaft of the generator.

The figures can be grouped in yet another way :—

Power absorbed in transmission	·211
Power lost in heat developed by resistances	·263
Power lost of necessity at the points of transformation...	·207
Power actually transmitted	·318
Total	1·000

The attention of makers should be given to these figures, and efforts made to minimise the losses so as to approach an efficiency of 50 per cent.

If we examine experiments IX. and X. in the same way we shall obtain these figures :—

Power expended in mechanical transmission.....	·209
Power lost in heat.....	·256
Power lost at the points of transformation	·212
Power actually transmitted	·314
Total.....	1·000

I would call the particular attention of electricians to this indication of the precise point where the loss of power which re-

Digitized by Google

mains to be studied is produced, a study which will prove of great interest. In every case we shall find in the preceding deductions a second and more precise example of the division of all the losses in the various parts of the transmitting apparatus. The electromotive force of more than 2,000 volts is very high for practical purposes, but it has enabled a power equal to nearly four horse-power to be transmitted to the exact distance predicted, a distance very nearly equal to 8·5 kilometres between the two stations (about 9305·60 yards).

ON SECONDARY BATTERIES.*

BY GEORGE F. BARKER, OF PHILADELPHIA, PA.

[ABSTRACT.]

A secondary battery is one which produces a current in consequence of a previous electrolytic condensation or polarisation upon the surfaces of its plates. Electrolytic polarisation and the production of a secondary current by means of it are almost as old as the voltaic battery itself. In 1801, Gautherot, having used platinum or silver wires as electrodes in a solution of salt, noticed a momentary inverse current when the battery was replaced by a galvanometer. Ritter observed the same phenomenon in 1803 with gold wires. He constructed a secondary battery with pieces of gold separated by cloth discs moistened with salt water. After contact for some seconds with a Volta's pile of more pairs than itself, it produced a current to which Ritter gave the name of secondary current. Platinum, gold, and silver gave a more marked result than copper, brass, iron, or bismuth; and no effect at all was obtained from lead, tin, or zinc. Fifty discs of copper separated by discs of cloth moistened with salt or sal ammoniac solution, when charged with a Volta's pile of 100 pairs, gave a current which decomposed water and produced all the effects of the primary current. Volta himself, as well as Marianini, explained the results by supposing that the decomposition of the salt produced acidic and basic deposits upon the metal discs; a view which Becquerel apparently confirmed by immersing a platinum plate in an acid and another in an alkali and noting that the current was the same in direction as the secondary current. But in 1826 De la Rive obtained the secondary effect from platinum plates immersed in dilute sulphuric acid; and since no basic or acidic deposits were now possible, he regarded the phenomenon as a physical one due to a special or polarised condition of the plates themselves. The current he called a polarisation current. In 1833-4, Faraday's researches on electro-chemical decomposition definitely established the proportionality of the current to the amount of electrolyte decomposed. He observed the "peculiar state" of the plates in his voltameter, and even noticed that when lead acetate was electrolysed, metallic lead was deposited on the negative plate and lead peroxide on the positive; but he offered no explanation of these phenomena. In 1842, Grove, following out an observation of Matteucci, constructed a gas battery in which the current was produced from two plates of platinum immersed in oxygen and hydrogen gases respectively. In 1852, C. W. Siemens used two carbon plates in lead acetate solution as a secondary battery; obtaining, by the action of the current, lead on one of these plates and lead peroxide on the other. One cell of this battery decomposed water; so that the electromotive force of the current must have been nearly two volts.

In 1859, Planté began an elaborate research upon this secondary action, studying carefully the influence of the metal and of the solution employed. The maximum effect was given by lead plates immersed in dilute sulphuric acid; and in 1860, he produced secondary batteries of remarkable power by rolling two sheets of lead together, a strip of insulating material being between them, and placing them in a ten per cent. sulphuric acid. When connected with a battery, the oxygen evolved upon the positive plate attacked it and converted its surface into peroxide; the hydrogen for the most part escaping. When now the current was reversed, the hydrogen reduced this peroxide to finely divided metallic lead and the oxygen attacked the other plate, producing peroxide. By such alternations, the metal may finally be corroded to any depth and the amount of finely divided lead and peroxide indefinitely increased. In Planté's experiments this forming process required three months. In 1881, Faure brought out a secondary battery in which, as in Planté's, lead plates in sulphuric acid were employed. But, in order to avoid the tedious process of "forming," in which the deposits upon the plates were produced by electric action, Faure covered the plates at the outset with a layer of minium or red lead. Upon passing the current, this red lead was reduced to metallic lead on the one plate and oxidised to peroxide on the other, thus producing the battery charged and ready for use in a single operation requiring but a few hours.

* From the *Proceedings* of the American Association for the Advancement of Science, Vol. XXXI., Montreal Meeting, August, 1882.

The theory of the storage of energy by secondary batteries is not difficult. Energy is capacity of doing work and work is force acting through distance. Whenever two attracting bodies are separated work is done upon the system and energy is absorbed by it; and this whether the attraction overcome is mechanical, molecular, or atomic. When an electrolyte is decomposed by an electric current, the current yields energy in proportion to the amount of the ions separated. The quantity of lead peroxide formed in a secondary battery represents the amount of energy stored from the current. So soon, however, as the separating force ceases to act the ions reunite and the stored energy becomes again free. Since the amount of energy thus set free, like that originally stored up, is proportional to the quantity of matter concerned, it is clear that the amount of electricity obtained from a given secondary battery is proportional to the amount of electrolytic products deposited upon its plates. In theory, the electrical energy set free should equal that originally stored up, but in practice this result is never attained.

In its primary expression the chemistry of the secondary battery is simple. In the form made by Grove two platinum plates are placed in acidulated water. Under the action of the current oxygen is set free on one of these and hydrogen on the other,* and the plates are said to be polarised. The electromotive force between these plates is the sum of the contact-potentials involved. Its value is 1·45 volt, and it measures the chemical attraction between oxygen and hydrogen. If now the two plates be connected by a wire the oxygen and the hydrogen recombine, and the energy of combination appears in the form of a secondary current. In general, however, the electrolytic action is accompanied by secondary chemical changes which render the phenomenon much more complicated. In the lead battery, for example, secondary products appear at both electrodes. The oxygen set free at the anode combines with the lead, the final product there being peroxide. The hydrogen evolved at the cathode reduces the oxide which it finds there and produces metallic lead. As before, the electromotive force in the battery is the sum of the contact-potentials, and this, in the case of lead and lead peroxide, is a little above two volts.† When now the plates are connected by a conductor the entire process is reversed. Water is decomposed, and, since the immersed portion of the plates changes sign on discharge, the hydrogen now goes to the peroxide surface and oxygen to the finely-divided metallic lead. The former is deoxidised to monoxide, and the latter oxidised to the same condition. Simultaneously a current flows through the conductor, the electromotive force of which is two volts, the strength of which is the ratio of this electromotive force to the resistances in circuit, and the duration of which depends upon the amount of secondary products deposited upon the plates during the charging. Beside this, however, another action takes place in the secondary battery which is of great importance. The sulphuric acid in which the plates are immersed attacks both the peroxide on the one plate and the metallic lead on the other, and converts both into lead sulphate. Moreover, as fast as the monoxide is produced by the discharge of the battery it is also converted into sulphate, so that upon complete discharge the plates are precisely alike, both being covered with lead sulphate.

The secondary batteries employed for experiment were those of Planté and Faure. Of the former type two cells of the larger size made by Breguet were used. Of the latter one cell of medium size made by Reynier and 34 cells of the size exhibited at the Electrical Exhibition at Paris were experimented with. The battery of 34 cells was made in January under my direction.‡ Each cell consisted of six plates each 20 by 60 centimetres, the lead being a millimetre thick. The exposed surface of each plate was, therefore, was nearly 0·25 of a square metre, and of each cell about 1·50 square metres. For the whole battery the surface was about 50 square metres (exactly 48·96). Each plate was covered on both sides with a coating of red lead about a millimetre thick made into a paste with water. Parchment paper was then folded over the whole, and over this a covering of felt sewed together at the edges. The plates were then folded transversely, and each pair intercalated. Heavy lead terminals were attached to each plate, and three pairs of plates were placed in each box, the terminals of one plate of each pair being united together and furnished with a connector. The boxes were lead-lined, and measured 31cm. in length, 25 in depth, and 11 in width. One of the two sets of plates was in contact with the lead lining, the other was insulated. The latter was always

* Undoubtedly the oxygen is produced by a secondary reaction.

† Planté observes that after complete charging the electromotive force may rise above two volts at the instant of removing the battery; but as it falls to this value at once on closing the circuit, and remains so, he attributes the first result to the temporary production of a peroxidised substance, as hydrogen peroxide or persulphuric acid, at the anode.

‡ This battery, as well as the cut-out, Fig. 1, was made by Jas. W. Queen and Co., of Philadelphia.

Digitized by Google

made the positive end. The total weight of a single cell was 17 kilograms.*

The charging current was generated by a Gramme machine whose field was maintained by an auxiliary dynamo. The maximum obtainable electromotive force of this current was 85 volts. In general, however, a much less electromotive force was used, sufficient only to give a current of from 10 to 20 amperes through the thirty-four cells arranged in series. Currents as high as 45 amperes, however, were occasionally employed. At the outset, considerable difficulty was experienced from the discharge of the battery when from any accidental cause the current fell below the potential of the thirty-four cells. The wear of the brushes of the auxiliary dynamo sometimes opened its circuit and thus destroyed the magnetic field of the Gramme. There being now no counter electromotive force to oppose it, the secondary battery current flowed back through the machine, discharging the battery completely. A simple device was arranged to prevent loss of the charge in this way should the charging current become weakened. This device is represented in Fig. 1, where A

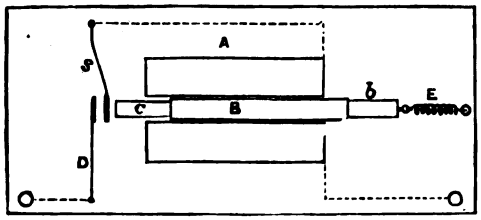

FIG. 1.

is a coil of No. 10 copper wire. Within its core is a rod of iron B, prolonged at both ends by brass rods of smaller diameter, *b* and *c*, these being supported upon rollers. Opposite the end of one of these rods is a flat spring S, faced with platinum and making contact when depressed with a similar brass strip D, also faced with platinum. The course of the current is shown by the dotted lines. When the circuit is closed between S and D, the current traversing the coil draws the iron bar strongly into its, axis, and the end of the brass rod pressing against S holds the circuit closed. Should the current weaken, the spring S reacts against the rod pushing it back and opening the circuit. By means of an auxiliary spiral spring, E, the instrument may be adjusted to any required current-strength. It would seem that by no possibility can the accumulated charge in the battery be lost, when this automatic cut-out is in circuit. As now described, the coil is of large wire, and the entire current passes through it.

(TO BE CONTINUED.)

IMPROVEMENTS IN DISTRIBUTING AND MEASURING ELECTRICITY, &c.

(CONCLUDED FROM PAGE 479.)

"In order to combine the advantages of comparatively high potential in the feeding conductors with lower potential in the houses in which the electricity is used a system of three conductors is used in combination with two dynamo machines coupled in series. This system is shown diagrammatically in Fig. 3, where A B represents the two dynamos, C D and E F represent the extreme conductors, which I will call the positive and negative conductors, and G H represents the intermediate conductor. The positive pole of the dynamo machine A is connected to the conductor C D, and its negative pole to the conductor G H. On the other hand, the positive pole of the dynamo machine B is connected to the conductor G H and its negative pole to the conductor E F. The houses to be supplied are divided into two approximately equal parts, preferably the houses being taken alternately. The houses of one part are supplied between the conductor C D and the conductor G H, and those of the other part between the conductor G H and the conductor E F. The intermediate conductor G H may be of much smaller dimensions than either of the other two, as it has only to carry the difference of current consumed by the two divisions of consumers, that is those connected with the conductor C D and those connected with the conductor E F. It need not be insulated, and, indeed, it may be replaced by the iron or other metallic covering often used to protect the copper conductors. In cases where the two divisions of consumers may be safely assumed to have a very approximately equal consumption at all times the intermediate conductor G H may be replaced in part by the earth, and the negative pole of the dynamo machine A and the positive pole of the dynamo machine B be connected together and to the earth."

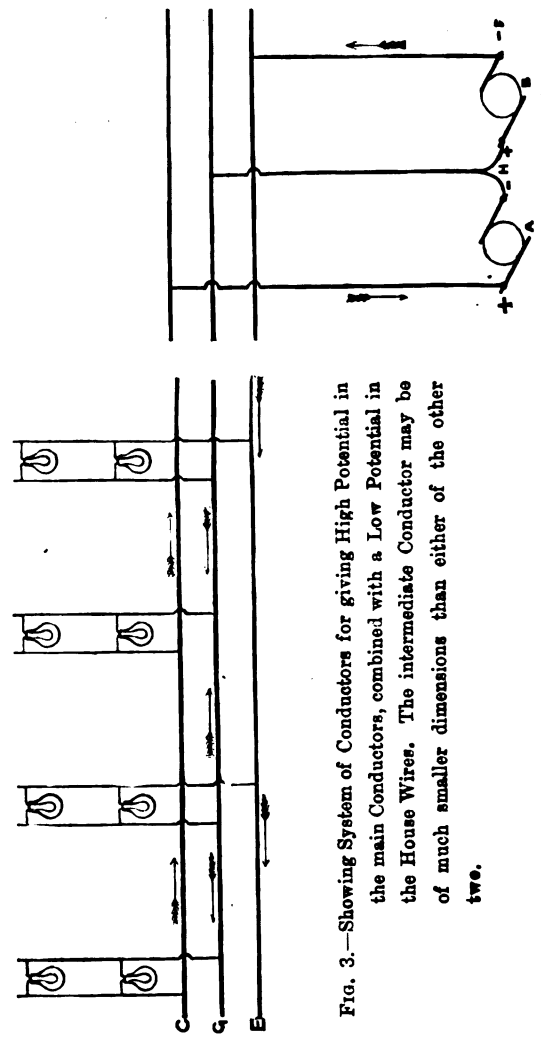

FIG. 3.—Showing System of Conductors for giving High Potential in the main Conductors, combined with a Low Potential in the House Wires. The intermediate Conductor may be of much smaller dimensions than either of the other two.

With regard to (2) measurement the apparatus described is an improvement upon previously designed apparatus. "In Fig. 4 the piece A is

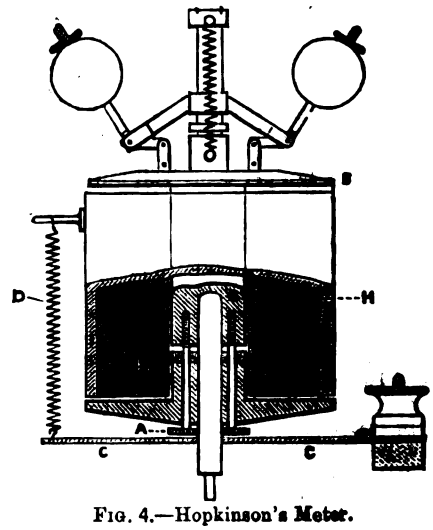

FIG. 4.—Hopkinson's Meter.

* Mr. W. Lachlan, the electrical engineer of the Light and Force Company, of New York, has kindly furnished me the following figures concerning the Faure batteries of improved construction recently imported in the steamer "Labrador." Four types of Faure batteries are made in Paris, called A, B, C, and D. Type A consists of seven positive plates, each 37 × 23·5cm. and 3mm. thick, perforated with holes 6mm. in diameter 10mm. apart, alternated with seven negative plates of the same size, but only 0·55mm. thick, and similarly perforated. The seven positive plates weigh 16·66 kilograms, the seven negative ones 2·77 kilograms. The rod lead spread on their surfaces weighs 22·13 kilograms, the two exterior plates being covered only on their interior surfaces, so that there are 26 active surfaces in all. Each plate has an electrode 7cm. wide. The box is 45 × 20 × 40cm. in size, is pitched throughout, and weighs with its cover 10 kilograms. The battery complete ready for charging weighs 63 kilograms. In type C there are five positive plates each 24 × 19cm., 3mm. thick, and four negative plates 0·5mm. thick, both perforated with holes 5mm. in diameter and a centimetre apart. The positive plates weigh 7·14 kilos., the negative 0·888 kilos. Sixteen surfaces are covered with red lead weighing 8·28 kilos. The electrodes are 3·5cm. wide. The box weighs 3 kilos., and the battery complete 20·37 kilos. Each cell of type A contains, it is claimed, when fully charged, 375 ampere-hours of current delivered at an electromotive force of 2 volts. Hence it will furnish, for example, a current of 25 amperes for 15 hours. Type C contains 150 ampere hours. Types B and D are round cells in jars of earthenware. The former weighs 35 kilos., and contains 225 ampere-hours; the latter 8 kilos, and contains 75.

Digitized by Google

carried by and revolves with that part B of the core of the electro-magnet H which is suspended from the governor, and it makes contact with the bar C, which is insulated and does not revolve. Thus there is always a rubbing when contact is made, which serves to keep the two surfaces clean. The insulated bar C is held up by the spring D. The other parts of the meter are similar to and act as described in Patent Specification No. 49, of the year 1882. When more than one dynamo machine supplies electricity to a system of distributing mains there is some difficulty in removing a machine from the circuit without a destructive electric arc being formed when the circuit is broken. This inconvenience is remedied by introducing into the conductor from the dynamo machine an instrument such as is shown in Fig. 5. A A is an electro-magnet in the circuit of the dynamo machine, its armature B carrying a piece C, making connection between D and E in the circuit. The connection between D and E is maintained so long as a certain current passes in the circuit, but when the current diminishes to a point below this limit the armature B and piece C drop, and the contact between D and E breaks. If it be desired to break the circuit of one of the dynamo machines it is only necessary to stop such

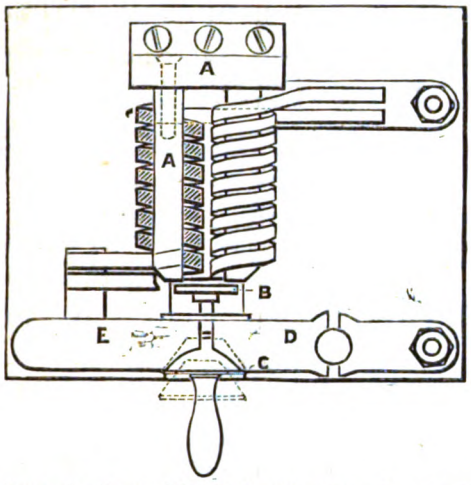

FIG. 5.—Apparatus for avoiding destructive Arcs when one Dynamo is removed from a Circuit in which are other Machines.

machine, and as its speed diminishes, at the right moment its automatic switch piece drops and the connection ceases. The form of the switch may, of course, be varied."

DIRECT SPANISH TELEGRAPH COMPANY (LIMITED).

The nineteenth ordinary general meeting of this Company was held at the offices, Leadenhall-buildings, Leadenhall-street, on the 31st ult., under the presidency of Mr. Edmund Etlinger (in the absence abroad of the chairman of the Company, Mr. Neil Bannatyne).

The MANAGER (Mr. Ch. Gerhardi) read the notice convening the meeting.

The CHAIRMAN said: I now suggest that the report and accounts should be taken as read. I propose to go *seriatim* through the various items, and to comment on them. The first paragraph states, "The annexed accounts for the half year ended 31st December, 1882, show a balance to the credit of profit and loss of £7,056 17s. 9d." This result, I need hardly tell shareholders who have been connected with the Company for some time, is very satisfactory. It represents, after paying the Preference dividend of 10 per cent., a distribution equal to 6 per cent. on the Ordinary stock, and consequently, if we had had no mishaps, we should probably have been able to recommend dividends of 10 per cent. on the Preference shares, and of 5 per cent. on the Ordinary shares, and to carry forward £1,000 to the reserve fund. We may, therefore, conclude that the half year was very satisfactory as far as traffics and profits are concerned. In the June half year the profit was only £5,889, and consequently the second half of the year to December was better than the first half year by £1,167. In the second paragraph of the report it is stated, "The receipts, although somewhat inferior to those of the last half year, are in excess of those for the corresponding period of 1881." In the June half of last year the receipts from telegrams were £11,300 against £10,841 in the past half year, and, consequently, there was an increase in the former period of some £500; but in spite of that, as I have said, the last six months' profit was better than that of the June half year. This is accounted for by reason of the repairs of the June half year having been heavy compared with the repairs of the December half year. That accounts for the fact that the profit is a good deal better, though the actual receipts from the transmission of messages were a trifle less. The traffic since the 1st January this year has been on the whole very satisfactory. For the month of January it was £1,658, for February it amounted to £1,459, and for March the receipts were £1,772, estimating those for to-day. For the three months, therefore, including the short month of February, the traffic amounted to £4,889. Last year, in the same period, we took £5,428, but then during the present quarter the Bilbao cable has been open only twenty-eight days. Owing to our joint purse arrangement we have received our income, though the cable was interrupted, but though a joint purse arrangement exists you do not, as a matter of fact, get your full proportion of the traffic. Many people, instead of going to the Eastern Company, go to the French cable in Paris, and many if they cannot telegraph direct will not telegraph at all. That accounts for our loss of traffic, though we have a joint purse arrangement; but with no such arrangement our traffic would have been very poor indeed. While on the subject of traffic I may point out that we have made considerable alterations since we last met. We met at Cannon-street last time, but we determined to come to this part of the town, as we knew that the greater part of the Spanish traffic came from this neighbourhood, and our idea, which has proved correct, was to attract traffic by coming here. We used to employ the Post Office for carrying our messages from London to Falmouth; but we have now contracted with the Post Office for a special wire going from this building to Falmouth, and it is there connected with our cable. From our office down stairs you can now telegraph direct to Madrid. This is an enormous improvement, and it has attracted a considerable increase of traffic. We have also a pneumatic tube by which all messages are whistled through from here to St. Martin's-le-Grand, and from there to here. We have, therefore, hired a wire and a tube. Before we entered into this arrangement we made elaborate calculations. We knew that we had to pay on every message we sent from here to Spain 1s., and also 1s. for every message that came on our cable in Spain for its transmission from Falmouth to London. These two items came to £2,400 a year. The whole of that we save. The hire of a special wire to Falmouth, the hire of a tube, and the extra rent we pay for this office and downstairs do not come to quite so much. There is, therefore, no loss on the arrangement, and we are located in the middle of the Spanish traffic. I think this arrangement has worked very satisfactorily, and that, in the long run, we must gain considerably from it. The report then says: "The Barcelona cable was broken down from the 8th to the 31st December. It was satisfactorily and economically repaired, and has since been in excellent working order. The cost of these repairs, £751 9s. 5d., was paid out of the revenue of the half-year." It is hardly a fact to say that a break is at any time a matter of congratulation, but, considering that this cable has been down nine years, and never cost us one farthing, I think we are very well satisfied in having a fault such as to cost us only £751. The fault was not at sea, but close in shore, and the cable had been eaten into. The cost of the repair was, however, very small, but the reason for that was that we received every assistance from the French Government, which enabled us to do the repair without sending out a ship from here. Had we sent out a ship the repair would have cost us about three times as much. This break made a little alteration in the traffic for January, but in February the traffic recovered itself, and for February and March the traffic was quite as good as before. The next paragraph in our report deals with the joint purse arrangement we made with the Eastern Telegraph Company. I think the circular we sent to all the shareholders informed them of the fact last year. It came into operation on the 1st of December, and we think it is an arrangement fair to both parties, and will work, as it has so far worked, very satisfactorily. I do not say that because our cable broke down, and we have received an income from the Eastern Company, but because we both save expense by not competing for the traffic, and employing agents. All that is saved, and each party receives its proportion of the traffic. At present the arrangement has worked more favourably for us, as our cable broke down, but to-morrow they may break down, and we should then have to work for them. As to the distribution of £7,056 profit, this is a subject on which I must speak with regret. We say in the report—"After paying the dividend on the Preference shares, amounting to £2,921 10s., and appropriating £200 to the reduction of the preliminary expenses account, there remains a balance of £3,935 17s. 9d. The directors deeply regret that they cannot recommend the payment of a dividend on the Ordinary shares, feeling the necessity of carrying the whole of this balance to the reserve fund, owing to the unfortunate interruptions of the Bilbao cable since the 1st January last, the repairs of which have to be provided for." Now, gentlemen, what has taken place since the 1st January has been a combination of misfortunes for us. In December last we discovered a small fault in the Lizard, close to the shore end; but that was nothing. The cable there is very much exposed to the sea. On the 14th of January, however, a break or fault was unfortunately found to exist in eighty fathoms of water, at about 145 miles from Bilbao, and at the same time another fault occurred 175 miles from Bilbao. We sent out a ship, which repaired first the break at the Lizard, and next the two other faults I have mentioned—at 145 and 175 miles from Bilbao. The ship had come back, but on the 9th March the cable again became interrupted. This time it was at twenty-two miles from Bilbao. The ship went out to repair that, and while she was out another fault developed itself about 140 miles from Bilbao; and the ship is out, having repaired the fault twenty-two miles from Bilbao, engaged on the repair of the fault 140 miles from Bilbao. The cost of these repairs we cannot quite tell, but as far as we can estimate them, they will not be less than £8,500. They may come to more, but I do not think we can expect them to be less. We have a reserve fund of £6,000. After paying our Preference dividend, and writing £200 off preliminary expenses, we have left £3,935 out of the profit of the last half year. We propose transferring that to the reserve fund, which will give us £9,935 to meet the cost of repairs. If we can do them for £8,500, we shall then have left £1,430, a very small amount—in fact, an almost inadequate amount—to reserve for contingencies. The directors, therefore, came to the conclusion to recommend you to forego a dividend for the present, trusting that the repairs will not occur so often on another occasion. It is quite possible that the present unfortunate breaks are an accidental combination of misfortunes at one and the same time, which may not occur again for a long period, but we ought not to shut our eyes to the fact that these repeated breaks indicate a mechanical deterioration of the cable. I do not think I have any further observations to make on the report, and as regards the balance-sheet I do not think there is much to observe. We have placed £395 and £221 in suspense. These items represent the expenditure we have incurred in removing from the other offices here, and in fitting up the special wire. It would not be fair to saddle those expenses upon one half year, and we therefore propose to wipe those amounts off gradually. In the profit and loss account you find that our expenses have slightly increased—by about £380. These items are accounted for chiefly by a small increase in salaries. On the whole, I may say, as to the expenses, that we have spent 28 per cent. of our gross receipts in working the Company, and in comparing that with the working expenses of any other company—except Atlantic companies, owing to the great lengths of their cables—it will be found that our expenses are quite reasonable. I now move that the report and accounts be received and adopted.

Mr. ABRAHAM SCOTT seconded the motion, which was carried unanimously.

The CHAIRMAN then moved the payment of a dividend at the rate of 10 per cent. on the Preference shares.

Digitized by Google

Mr. SCOTT seconded the resolution, and it was carried unanimously.

On the motion of Mr. DYETT, seconded by Mr. COCHRAN, the retiring directors, Messrs. Etlinger and Scott were re-elected; as was also the auditor, Mr. Herbert R. Duke.

The CHAIRMAN then expressed a hope that when the engineer returned home with the ship he would give a tolerably good account of the cable. If necessary, the directors would let the shareholders know how things were going on.

Mr. BRAMLEY then moved, and Mr. LOW seconded, a vote of thanks to the chairman and directors, which was carried.

The CHAIRMAN, in acknowledging the vote, stated that the directors had been connected with the undertaking from the very beginning. They took a great interest in it, and their joint holdings were very considerable. Naturally, therefore, they did all they could to keep down the expenditure.

The proceedings then terminated.

ELECTRICAL POWER STORAGE COMPANY (LIMITED).

An extraordinary general meeting of the shareholders was held at the offices of the Company, 4, Great Winchester-street, on Thursday, Sir Daniel Cooper, Bart., K.C.M.G., in the chair.

The SECRETARY (Mr. Holland Dell) read the notice convening the meeting, and the minutes of the preceding meeting, which were confirmed.

The CHAIRMAN said: This meeting has been convened to submit for confirmation the resolutions passed at the meeting of the Company held on the 21st March. I will put them in the shape of two resolutions, as the last alteration should be put specially by itself.

The resolutions, the effect of which has been published in *The Electrician*, were then separately confirmed unanimously.

The CHAIRMAN: It is not usual at these confirmatory meetings to give any information; but if I had to give any information it would be favourable. The business of the Company is going on all right, and I hope we shall have a good story to tell you when we next call you together.

The meeting then closed.

MONTEVIDEAN AND BRAZILIAN TELEGRAPH COMPANY.

The ordinary general meeting of this Company was held on Thursday, at the offices, Tokenhouse-buildings, Moorgate-street, and the report which was presented to the meeting for the year ending December 31st last stated that "the Company's percentage of the gross earnings of the Western and Brazilian Company amounts for the year to £2,769 18s. 3d., the December quarter being estimated at £745. After setting aside £500 for redemption of debentures, and providing for all charges and debenture interest accruing during the year, there remains a net balance of £940 16s. 7d., out of which it is proposed to pay a dividend of two shillings per share (£1 per cent.) and carry forward a balance of £109 8s. 7d. to next account."

SUBMARINE CABLES TRUST.—Notice is hereby given that the COUPONS of the SUBMARINE CABLES TRUST, due on the 15th instant, will be PAID on and after MONDAY, the 16th instant, by Messrs. GLYN, MILLS, and CO., of 67, LOMBARD-STREET, between the hours of 10 a.m. and 2 p.m.

The Coupons must be left for examination three days previous to calling for payment.

LEWIS WELLS, Secretary.

66, Old Broad-street, E.C., April 2, 1883.

CITY and GUILDS of LONDON INSTITUTE for the ADVANCEMENT of TECHNICAL EDUCATION.

TECHNOLOGICAL EXAMINATIONS, 1883.

Examinations in Technology will take place at the different provincial centres throughout the kingdom on WEDNESDAY EVENING, May 30th, 1883, at 7 o'clock.

Secretaries are informed that the latest date for sending in returns of Candidates who wish to be examined in May next is SATURDAY, April 28th, after which date no application can possibly be received.

Individual Candidates who are unable to arrange to be examined at a provincial science centre can, on application to the Director and Secretary, be examined in London at the Finsbury Technical College, Tabernacle-row, E.C.

The examinations will be held in 42 subjects. A Programme, containing Syllabus of each subject and last year's examination questions, can be obtained from the Central Office of the Institute, Gresham College, London, E.C.

PHILIP MAGNUS, Director and Secretary.

MOST IMPORTANT SALE BY TENDER.

IN THE MATTER OF
THE DUBLIN ELECTRIC LIGHT COMPANY (Limited),
IN LIQUIDATION.

TO BE SOLD:

LOT No. 1.—The PREMISES situate at GREAT BRUNSWICK STREET, in the City of Dublin, lately known as "Farrell's Horse Repository." This is one of the most central positions in the city. The premises are held by the above Company under leases for a long term of years unexpired, subject to the almost nominal rent of £110 per annum. A portion of the premises has been taken by the Corporation of Dublin; £1,881 is to be paid by them therefor, and the purchaser will be entitled to this amount.

LOT No. 2 (AS A GOING CONCERN).—The INTEREST and GOODWILL of the Company in the Premises situate at Liffey-street and Fade-street, with the PLANT, MACHINERY, FIXTURES, FITTINGS, and LICENCE to use the "BRUSH" MACHINES and APPLIANCES.

This Company has been for the last 18 months supplying Electric Light in the City of Dublin, and the business is, at present, in full working order. Having regard to the extensive orders which the Company was called upon to execute, and to the growing desire to avail of the advantages of the Electric Light, there is a large field for successful enterprise open to any one possessing sufficient capital to supply the requirements of the public.

Sealed Tenders for the Two Lots, or for each Lot separately, will be received by the Liquidator, Mr. ROBERT GARDNER, up to 12 o'clock on SATURDAY, the 14th day of April next, at which hour they will be opened by him in the presence of the parties attending, and the Purchaser declared.

For Statement of Title, Conditions of Sale, and any further information, apply to

Messrs. CASEY and CLAY, Solicitors,
21, St. Andrew-street, Dublin; or to
ROBERT GARDNER, Liquidator,
Trinity Chambers,
40 and 41, Dame-street, Dublin.

March 28th, 1883.

FAURE-SELLON-VOLCKMAR ACCUMULATORS.

On and after 1st January, 1883,
THE
ELECTRICAL POWER STORAGE COMPANY
(Limited),
4, Great Winchester-street Buildings, E.C.,
will be prepared to supply
FAURE-SELLON-VOLCKMAR ACCUMULATORS.

Which can be used in conjunction with any Incandescent Lamp or Electrical system, and afford the only reliable and economical means of lighting Private Houses, Hotels, Theatres, Ships, Railway Carriages, &c., by Electricity.

Particulars and prices post free on application.

A YOUNG GENTLEMAN, with a thorough knowledge of the Brush system of Electric Lighting, desires an ENGAGEMENT as ELECTRICAL ENGINEER.—Address, J. H., "ELECTRICIAN" Office, 386, Strand, London.

ELECTRICIAN and MANAGER.

WANTED, by an Electric Light Company, a competent ELECTRICIAN and GENERAL MANAGER. He must be willing to canvass for customers, and to assist generally in promoting the business, and must be fully competent to undertake the management of the installation in all respects. Salary, £200 a year. Address, by letter, stating age, references, and qualifications, on or before the 11th April, to SECRETARY, Hastings and St. Leonards Electric Light Company, 62, Cambridge-road, Hastings.

FACTORY and WATERSIDE PREMISES to be LET, or the LEASE at £200 per annum rent to be SOLD. First class premises, with a frontage of about 40 feet to the canal, and 40 feet on the other side to the road. Depth about 90 feet, ground floor of factory, with two floors above 18 feet by 85 feet. Steam power on the premises, to be taken at a valuation. Situate close to King's-cross. Apply to the SECRETARY of the London General Cab Company, 68, York-road, King's-cross, N.

SLIP

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending April 6 were £3,521.

SOLENOID.—It may be news to some of our younger readers to know that our word solenoid is derived from the Greek σωλην, a tube.

CHARING-CROSS ELECTRIC RAILWAY.—The Charing-cross and Waterloo Electric Railway Bill was read a second time in the House of Commons on Monday last.

THE BRUSH SYSTEM IN ABERDEEN.—The experimental lighting of certain streets in Aberdeen by the Brush system, which has continued for three months past, is to be extended over another four weeks.

INSTITUTION OF MECHANICAL ENGINEERS.—At the ordinary general meeting of this institution, held on Wednesday and Thursday last, a paper, by Mr. A. C. Bagot, on "The Application of Electricity to Coal Mines," was to have been read.

THE TELEPHONE IN HOLLAND.—The Bell Telephone Company, established in Holland in December, 1880, has, at the present time, 915 subscribers; in Rotterdam, where the company started on the 1st March, 1882, there are already 378 subscribers.

KING'S COLLEGE, LONDON.—We understand that Professor W. Grylls Adams, F.R.S., will continue his course of lectures on electricity (voltaic and dynamic) and magnetism during the ensuing term. Further information can be had of the secretary, Mr. J. W. Cunningham.

THE GENERAL TELEGRAPHIC NEWS COMPANY.—An extraordinary general meeting of this company is to be held at 17, Cornhill, on the 3rd May, at 2 p.m., to receive an account of the winding up of its affairs, and the disposal of its property from the liquidator, Mr. W. King.

THE QUESTION OF THE WIRES.—The Marylebone Vestry have resolved to send a deputation to wait on the Government with reference to the liability of local authorities for the safety of over-head wires, and as to whether they have the power to stop the erection of such wires.

NEW COMPANY.—The American Postal Telegraph Company was incorporated at Albany, New York, on the 28th March. It is formed for the purpose of buying, constructing, owning, using, and maintaining telegraph lines throughout the State of New York. The capital is 5,000,000dols.

THE POST OFFICE RIFLES.—At a full dress parade of the 24th Middlesex (Post Office) Rifles, held at St. George's Barracks, Trafalgar-square, W.C., on Wednesday morning, Major General Higginson, C.B., distributed the Khedive's Bronze Star to those members of the corps who took part in the Egyptian campaign.

DIRECT UNITED STATES CABLE COMPANY.—This company notify that the half-yearly interest on their Six per Cent. Debenture Loan will be paid on and after the 16th inst. at the Consolidated Bank, Threadneedle-street, E.C., where coupons should be left for examination three clear days before applying for payment.

THE SOUTH AFRICAN CABLE.—The Eastern Telegraph Company notified the interruption of the Eastern and South African Telegraph Company's cable between Zanzibar and Mozambique on the morning of the 6th inst. The company's repairing ship stationed at Zanzibar was to proceed as quickly as possible to restore telegraphic communication.

ANGLO-AMERICAN TELEGRAPH COMPANY.—The directors of this company have resolved, after placing the quarterly sum of £37,500 to the credit of the Renewal Fund, to declare an interim dividend for the quarter ending March 31, 1883, of 15s. per cent. on the Ordinary and 30s. per cent. on the Preferred stocks, both free of income-tax, payable on the 1st of May.

SOCIETY OF ARTS.—The following are the dates and arrangements for the forthcoming meetings of the Society of Arts:—Ordinary meetings, Wednesdays—April 18, "The Government Patent Bill," by H. Trueman Wood, B.A., Secretary of the Society. Applied Chemistry and Physics Section, Thursday—May 24, "The Development of Electric Lighting," by J. E. H. Gordon, B.A.

SIXPENNY TELEGRAMS.—It is rumoured that great efforts will be made during this year to increase and extend the wire accommodation of the Postal Telegraph Service, in view of the anticipated reduction of rates. Something like a quarter of a million, it is expected, will be required for this purpose. The construction staff of the engineering branch are expecting to be deprived of their annual leave this year.

PERSONAL.—It is stated that Her Majesty has signified her intention of conferring the honour of knighthood on Mr. Richard Henry Wyatt, for twenty-five years parliamentary agent to the Treasury. Amongst the important acts which Mr. Wyatt has helped to carry through Parliament was that relating to the telegraphs; for his services in regard to this matter, Mr. Wyatt received the thanks of the Postal Department.

LOUIS MAICHE.—In its issue for the 7th inst. our contemporary, *L'Electricité*, gives a biographical notice, with a portrait, of this well-known electrician. It appears that he was born at Mans on the 22nd June, 1843, and is, therefore, not forty years old yet. Our contemporary gives a list of M. Maiche's inventions, amongst which are batteries, electrophones, and other electrical apparatus and applications of electricity.

THE FRENCH ACADEMY OF SCIENCES.—The Academy have postponed the award of the Boidin prize, consisting of a gold medal and 3,000 francs, until 1885, on the ground that the essays did not conform to the conditions laid down. Seven essays were sent in, and one, "On the History of Storms," was awarded 1,000 francs for merit. The subject set was "The Origin of Atmospheric Electricity and the Development of Electrical Phenomena in Storm Masses."

"ANNALES DE L'ELECTRICITE."—It may be interesting to our friends to know that, as a rule, more than 50 per cent. of the matter contained in this publication is taken *without acknowledgment* from our pages. Perhaps literary honesty will go still further, and we shall in a few weeks have to notice that some friendly hand simply reproduces our pages entirely, and without acknowledgment. Five consecutive pages, including our last special supplement, will be found in the issue for March 31. After this our American friends must stand in the background.

THE UNITED TELEPHONE COMPANY.—The officers and *employés* of this company on Tuesday last presented to their chairman, Mr. James Brand, through their managing director, Mr. Joseph B. Morgan, a handsomely-illuminated address. The address stated that it was felt that the rise, progress, and development of the United Telephone Company were mainly owing to the indomitable energy, pluck, and manliness which had been shown by the chairman, coupled with an honesty of

Digitized by Google

purpose that had confounded the enemies and increased the friends of this novel undertaking.

THE CZAR'S CORONATION.—*The Times'* St. Petersburg correspondent, telegraphing on Tuesday last, says:—"The work of preparation at Moscow goes on apace. The walls and towers of the Kremlin are to be illuminated throughout with various coloured lamps, while the towers of the Assumption and of John the Great are to be outlined with 3,500 Edison lights, and four electric suns, of the power of 40,000 candles each, are being placed on the four turrets on the outer walls. The Moscow palaces and the house of the Minister of War are being connected by telephone."

PREVENTION OF COLLISIONS AT SEA.—The Council of the Society of Arts have appointed a committee to consider the question of preventing collisions at sea. The work of the committee will be confined to a consideration of the best means of preventing collisions in fogs. The committee will be glad to receive any information on this subject from persons who have given their attention to it, or to consider any proposals having for their object the prevention of such collisions. All such communications should be addressed to the Secretary of the Society of Arts, John-street, Adelphi.

INDO-EUROPEAN TELEGRAPH COMPANY.—The directors of this company have determined, after setting aside £5,000 to the reserve fund, providing for freeholds and stores, £8,301 on maintenance account, and for a payment to the India Office of £6,500 on account of the Persian Debt in the nature of a reserve fund, to recommend the payment for the six months ending the 31st December, 1882, of 17s. 6d. per share, making, with the interim dividend already paid, 6 per cent. for the year and a bonus of 15s. per share, carrying forward £1,900 to the next account.

DISPLAY OF AURORA.—The following account of a display of aurora, which was witnessed at Kirkwall on the night of Tuesday week (April 3), is taken from an Edinburgh paper:—"Shortly after nine o'clock the sky in the north, east, and west assumed a light yellowish colour. Streamers began to rise, rather faintly first, but afterwards they would ascend from the horizon and meet in the zenith, diffusing most beautiful colours. About half-past eleven o'clock clouds in the north appeared to change to an inky colour. Streamers now changed to flashes, going with the rapidity of lightning, the effect being most beautiful. The display of aurora has been very common in Orkney this season."

THE EDISON SYSTEM IN AMERICA.—Recent advices from the United States state that an Edison Electric Illuminating Company has been formed in Boston, Massachusetts, with a capital of 1,000,000dols., and that a central station was to be established at once capable of supplying 20,000 lights. Another company with a similar title has also been organised in Danville, Pennsylvania, where also arrangements are being made to start a station. The Western Edison Company of Chicago are stated to have secured a contract for putting their lamps into the Merchants' National Bank in that city, and are also putting down isolated plant in Haverley's Theatre and the American Express Building there.

INTERNATIONAL ELECTRIC EXHIBITION, VIENNA.—We learn that in consequence of the intervention of the Austro-Hungarian Embassy at St. Petersburg, and a report from the Russian Minister of Finance, the Emperor of Russia has granted the Imperial Russian Technical Society of St. Petersburg the sum of 15,000 roubles, to aid in the formation of a Russian section at the International Electric Exhibition at Vienna. At a meeting held on 19th March (old style), the president of the above-mentioned society, Prince Kotschubey, informed the members of this imperial resolution, and the chairman of the electrical section, Mr. Welitschko, who represented the Russian Government at the Paris Exhibition in 1881, has been entrusted with the organisation of the Russian exhibits.

AN EXTRAORDINARY RUN.—We are informed that an extraordinary run was recently made by an engine attached to one of the steam dynamos in the Edison Central Station, Pearl-street, New York, which ran for seventeen days and nights successively with a load varying from a minimum of 40 horse-power to a maximum of 150 horse-power indicated. The engine which accomplished this feat is a "Lawrence" direct acting high speed engine running at 350 revolutions per minute, made by Messrs. Armington and Sims, of Providence, R.I. If we suppose the engine to have had a five-feet driving wheel attached, this performance would have been equivalent to that of a locomotive making the circuit of the globe at the equator. It should be added that the bearings of the engine when stopped were not found to be unduly heated.

TELEGRAPH CLERKS AT DUBLIN.—In the House of Commons on Monday night, Mr. O'Donnell asked the Postmaster-General if he had received a petition from clerks in the Postal Telegraph Department, Dublin, asking for an annual holiday equal to the annual holiday enjoyed by postal telegraph clerks in London; and what reply he had given to the petition. Mr. Fawcett replied that two years ago an application was received from the telegraph force in Dublin requesting that those of their number who were in receipt of £2 a week and upwards might be granted one month's leave in the course of the year, and in May last it was announced to the service generally that no extension of the annual leave could be granted. Since then no application on the subject had reached him from Dublin. He added that in Dublin the period of annual leave is practically the same as in London—viz., for superintending officers, one month; for telegraphists who have Sunday and night duty, three weeks; and for others, one fortnight.

TATE'S ELECTRICAL ENGINE STOPPER.—At a recent meeting of the Royal Scottish Society of Arts, at Edinburgh, the report of a committee which was appointed some time since to examine and report upon Tate's electric valve-closing apparatus was submitted. The report stated that this invention seemed admirably adapted for the purpose specially in view—viz., the immediate stoppage of machinery in the event of an accident, either to the machinery itself or to persons employed. The value and importance of an arrangement, the report proceeded, by which the actuating power in large mills could be rapidly controlled and brought to a stand, could not, in the opinion of the committee, be overestimated. The facility with which this could be accomplished from any part of the factory, however distant from the engine, by the easy and instant application of electricity in the mode proposed by Mr. Tate, appeared to them to merit the highest commendation of the society. This apparatus was described and illustrated in our issue for October 24, 1882, p. 535 of Vol. IX.

TELEGRAPH WIRES STRUCK BY LIGHTNING.—We have received the following account of the destruction of a considerable length of telegraph wire during a thunderstorm which occurred in Cyprus on the 1st of March from a correspondent who was an eye-witness of the occurrence. He says:—"On the 1st inst. (March), near the village of Lacofranco, a flash of lightning struck the line wire about midway between two poles. The current divided and rushed

Digitized by Google

along the wire to either pole, completely destroying the whole of the wire short up to the insulators, where, with a loud report, it jumped to the iron poles and made earth. The length of wire destroyed was 85 yards. The size of wire was No. 8 B.W.G. galvanised iron. The two ends have a purplish hue, and are like hardened steel. The cups of the insulators (white porcelain) were broken, the upper parts being covered with a purplish metallic-looking coating radiating from where the line was attacked. The coating is thoroughly burnt into the glaze of the porcelain. The inside of the cups nearest to where the electric fluid sprang from the line to the iron pole is covered with a fine dark metallic-looking deposit, which is also burnt into the porcelain."

Calcutta International Exhibition.—Communications recently received from the Vice-President of the Executive Committee at Calcutta (the Hon. Colonel S. T. Trevor, R.E., joint secretary, Government of Bengal, Public Works Department) are to the effect that all the necessary annexes in course of erection adjacent to the India Museum in connection with this exhibition will be completed by July or August. A large space on the Maidan, facing the musem, has been enclosed, and will be devoted specially to machinery in motion, agricultural implements, &c. Gas and water will be available throughout the building. The arrangements in regard to lighting are now under consideration. It is proposed that, for this purpose, the electric light should be employed. A deep reservoir, covering an area of nearly 90,000 square feet, will serve for exhibiting specimens of native boats, and for displaying diving apparatus, life-saving apparatus, including boats and steam launch mahinery. The Public Works Department of the Government of India has communicated with the governments of the several presidencies and provinces requesting them to obtain from the railway authorities under their control special rates for the carriage of goods intended for the exhibition. The interest shown in the undertaking by the foreign consuls, and the number of applications for space received from all parts, ensure the complete success of the exhibition as an international display. In considering the allotments of space, priority will be given in accordance with the dates of the applications received through the official agent, 4, Westminster-chambers, Victoria-street, London.

Lightning Conductors.—Something recently stirred up the good people in Edinburgh to inquire into the condition of the lightning conductor supposed to keep guard over the spire of the General Assembly Hall in that city. Accordingly a "steeplejack" was called in and sent to the top of the said spire, some 240 feet above *terra firma*, with instructions to attach a copper wire to the upper end, and thus enable the conductor to be tested. The latter appears to have been put up some 28 or 29 years ago, and to have consisted of a $\frac{3}{4}$in. copper rod, connected by screwed joints. Upon testing the conductor, by sending a current through it *viâ* the copper wire, its resistance was found to be as much as 800 ohms, at least, so our contemporary, the *Scotsman*, states. This was, of course, sufficient to condemn the rod at once, and accordingly arrangements were at once made to fix a new copper wire rope conductor, five-eighths of an inch in diameter, which, after reaching the ground, was carefully soldered to a water main. When this was completed, the resistance of the metallic circuit, consisting of the test wire and the new lightning conductor, was discovered to be somewhat less than three-tenths of an ohm; and when the earth connection was included in the circuit the resistance did not exceed one ohm. It may, therefore, be assumed that the spire is now, for the first time, thoroughly protected against lightning, while the condition of the new conductor can be learned at any time without undertaking the serious task of ascending to the top of the spire. The work has been satisfactorily executed by Messrs. Ritchie and Son Leith-street, Edinburgh, under the direction of Mr. Robertson, of Her Majesty's Office of Works. We have frequently alluded to the urgent necessity for periodical tests being made of the conductivity of lightning rods. There are many conductors in no better condition than that mentioned above, and which, instead of being a safeguard, are positively dangerous.

The Cost of Gas Lighting.—The following figures, taken from a report recently presented to the Streets Committee of the Commissioners of Sewers by their engineer, Colonel Haywood, will prove of interest to electric light engineers, though they deal wholly with gas lighting. The report relates to the experimental lighting of Fleet-street by Messrs. W. Sugg and Co., which was commenced some few months ago. It appears that each lamp encloses three flat-flame governor burners, two of them consuming 10, and one 5 cubic feet of gas per hour. They are so arranged that the central burner can be kept lighted, and the two outer ones extinguished. The illuminating power of each lamp, when the three burners are fully lighted, is stated by Messrs. Sugg and Co. to be equal to 80 candles. The 5ft. bat's-wing burner in common use in the City is said to produce a light equal to about 14 candles. The illuminating power of the improved lamps is, therefore, about five and three-quarter times that of the ordinary burners. The relative cost of lighting Fleet-street appears to be as follows:—By the system generally in use, the cost of each lamp, including lighting and extinguishing, is now £4 10s. 4d per annum, or a total charge of £126 9s. 4d. for the 28 lamps. By the experimental system (one 5ft. burner only being alight after midnight), the cost as given by the gas company is 67,820 cubic feet of gas per annum, at 3s. 2d. per 1,000 = £10 14s. 9d.; lighting, extinguishing, and maintenance per lamp, £2 5s.; total per lamp per annum, £12 19s. 9d.; total for 28 lamps per annum, £363 13s. The expense by the ordinary system being £126 9s. 4d., and by Messrs. Sugg and Co.'s system £363 13s., it appears that the latter is 2·87, or nearly three times the cost of the former. The general result appears to be that Messrs. Sugg and Co.'s system gives between sunset and midnight about five and three-quarter times as much light, and between midnight and sunrise the same light as the ordinary lighting does, and at about three-times the cost of the ordinary lighting. The cost of lighting the arterial thoroughfares in the City varies considerably, according to the widths of the streets, but may be taken on the average at about £530 per mile by the present system, and it would be about £1,500 per mile according to the experiment now under trial in Fleet-street.

Fast and Slow Telegrams.—A Proposal.—In *The Times* of Monday last, Mr. Latimer Clark makes the following proposal:—"As there is a near prospect of a reduction in the cost of telegrams," he says, "it appears a suitable time to call attention to the advantages, as well as the economy, which would be obtained by a division of messages into two classes, slow and fast. The effect of employing the telegraph as the ordinary medium of business communication, and of thereby doubling and quadrupling the present number of messages, must be to crowd the lines with work and to greatly retard the time of delivery, so that we must no longer count on that celerity of transmission which has hitherto constituted the distinguishing feature of the telegraph, and which has given it such inestimable value. In-

Digitized by Google

crease in the staff and number of wires and the use of the best modern appliances will do much to remedy the evil, but the space available for poles or wires is limited, while the increase of telegraphy has not yet approached any limit. I would, therefore, advise that two classes of messages should be introduced—express telegrams and ordinary elegrams, corresponding in their use to the express trains and goods trains on a railway. The express telegrams, written on paper of distinguishing colour, should take precedence in transmission over ordinary messages everywhere and at all times; the ordinary traffic should only follow in its turn. The price of the express telegrams should, I think, be so regulated that they should not form more than from 5 to 6 per cent. of the whole traffic, and to effect this I assume that it would be necessary to charge at least eight or ten times the ordinary tariff. On the other hand, if the price were so regulated that they formed about 20 per cent. of the whole number, the receipts would be so much increased that it is probable that the introduction of sixpenny telegrams might be effected without any sensible loss to the revenue, or without any sacrifice of speed in those cases where rapid transmission is desired and is worth paying for. While introducing sixpenny telegrams, I assume, as a matter of course, that the opportunity will be taken of abolishing the custom of writing the address in the form from A to B, and of thus giving two addresses gratis. The address should be similar to that of an ordinary letter, and the address of the sender should form part of the message, as is done in all other countries." Our readers will find this question dealt with in our leading article.

The American Bell Telephone Company.—At the annual meeting of this company, held at Boston on the 27th March, it was stated that the total earnings for the year amounted to 1,576,031·57dols., against 1,001,924·91dols. in the previous year. The expenses were 603,987·29dols., against 439,862·76dols. for the year preceding; net earnings for the year, 972,044·28dols.; balance of income from previous year, 126,034·58dols.; total, 1,098,078·86dols. The total of the previous year was 606,555·01dols. Dividends paid, 595,000dols.; carried to surplus account, 334,997·32dols.; balance of income account, 168,081·54dols.; total, 1,098,078·86 dols. The sales of instruments for export had decreased, and were likely still further to decrease, as foreign countries were making good instruments of their own. The royalties from manufacturers now go to the manufacturing branch. Local companies in New York, Chicago, San Francisco, and Boston were all paying dividends. All of the Dominion of Canada, exclusive of Newfoundland, was supplied by the American Bell Company, and dividends were to be expected from Canada. The legal expenses of the company had been heavy during the year. The report of the treasurer congratulated the company on the fact that the courts had decided that the Dolbear condenser telephone receiver, so-called, infringes on the Bell patent, and an injunction had been issued; also upon the opinion of Justice Gray that the Bell patent had all the breadth that had been claimed for it, and covered microphones and instruments that employ electrical undulations. The People's Telephone Company, using a carbon transmitter, had set up lines in New Jersey, and the report stated that an action on the case called forth the most careful examination that had ever been given to the principles of the various instruments, and gave additional proof that the microphone and other things claimed under the Bell patent were authorised. The case had since been decided in favour of the Bell Company. The underground wires in Boston had been found to transmit distinctly only for short distances, and it would be necessary to devise further improvement before they could be made available to any extent. It was voted that the capital stock of the company be increased from 7,300,000dols. to 9,800,000dols., and that new shares be allowed on the basis of one new share to each holder of the old ones. Incidentally it was mentioned that no less than two million miles of overhead wires had been added to the company's system during the year.

Electric Lighting and the Board of Trade.—The following letter from Mr. E. H. Johnson, vice-president of the Edison Company of New York, appeared in *The Times* of April 7. It has reference to letters from Mr. Arnold White, secretary of the English Edison Company, and Mr. Mackenzie, of the Metropolitan Brush Company, which appeared in previous issues of *The Times*, and the former of which we reproduced at page 479 of our last issue. Mr. Johnson says:—"The essence of the question seems to be—What method of charge will best develop and insure to the users of the electric light the benefits of economic improvements? This question resolves itself into two heads. First, whether the development of the burners be the best promoted by a method of charge which interests the undertakers in its economy, or by that which, as in the gas system, enlists them on the side of its wastefulness. In the first case, the development of the burners would yield to the undertakers an increased profit, while in the latter case it would reduce the profit. In the one case the price is reduced by virtue of the higher producing power of a certain investment and by greater consumption; in the other only by reason of the greater consumption. The theory of the parliamentary Bill, that the development of the burner will be best effected by leaving it to the general public rather than to those more vitally interested, would seem to be sufficiently contravened by the history of the gas burner, the development of which has only become active with the introduction of the incandescent lamp, thus proving that the public have left its improvement to the gas undertakers, and they now only take it up in self-defence. I maintain, therefore, that the improvement of the electric burner will be more rapid in the hands of undertakers whose dividends depend upon it than if left to the general public, which can only reap a benefit in its individual capacity. The argument that the public does not benefit by the increased dividends of the undertakers does not avail against my proposition, since legal limitation and competition as between the electric light companies and the gas companies will compel the undertakers to divide with the public by a gradual reduction of the price. Secondly, whether best check is had upon the undertakers by a system of charging for that which is actually bargained for—*i.e.*, light, or by a system which, like the gas system, sells to the consumer something from which he may in his own way produce light. In the one case he has only to measure the final product. In the other he has a more or less reliable record of the number of units of energy from which he has obtained an unknown quantity of light. But Mr. Mackenzie asks, 'How can we measure it?' The plan is a simple one. The lamps provided by the undertakers are rated at so many candles each. Their consumption of energy is definitely known and fixed with a current of a given strength. Thus, in the Edison system the standard lamp is of 16 candle-power. This lamp requires three-quarters of an ampere of current to yield 16 candles of light per hour. The bill to the consumer is based upon these known standards. If the consumer has reason to question the accuracy of his bill, he has only to count the number of lamps in use for a given number of hours, multiply the two together, and the total by 16 (the standard of the lamp), and he will have

Digitized by Google

an absolute check. For illustration, the undertakers present a bill for 48,000 candles of light. The consumer counts his lamps and takes note of the number of hours they burn, and finds that he has 10 lamps burning 10 hours per day, or one lamp for 100 hours. This for 30 days gives him 3,000 lamp hours. This, multiplied by the company's own standard of 16 candles, yields 48,000 candles, and he has proof positive that the bill is correct. If the bill were more, he has proof of its error, which the undertakers would be bound to accept, since no matter what number of amperes of current the meter may have shown to have passed, the calculation of the amount of light supplied is made from the basis of so much current per lamp to produce 16 candles of light per hour. If the undertakers object to the consumer's count, they can make it themselves, or in other ways test the accuracy of their meter. Compare this with the check upon a gas meter. The bill is for 2,400ft. of gas. An examination of the meter shows the record to be in accord, but does that prove that the consumer has had 48,000 candles of light? No; the larger proportion of his gas may be escaping and not supplying light at all. Or, if not escaping, his burners may be so wasteful that, instead of getting 16 candles from a 6ft. burner, he may, as we all know, be only getting eight or ten. Why, then, perpetuate a crude and imperfect system offering no real check when a perfect and absolute one is available? The candle-power of the lamps may be tested in many ways, but this like many other details takes care of itself where the undertakers are interested in their efficiency. If the lamps were under candle-power it would be because an insufficient current was passing through them. This would show upon the meter; and the bill would be proportionately decreased—a matter which the undertakers would speedily remedy in their own interests. If they were above their proper standard, thus giving the consumer more light than he desired to pay for, the lamps would be more quickly destroyed, and since the Edison system contemplates the supply of lamps free of charge to the consumers, it would speedily remedy this defect to save itself a heavy charge for lamp breakage."

Electricity Afloat.—Many of our readers are, no doubt, familiar with the outward appearance of H.M.S. "Rainbow," the head-quarters of the members of the 1st London Corps of the Royal Naval Artillery Volunteers, which lies at her moorings off the Victoria Embankment, a short distance below Waterloo Bridge. The old boat (she served in the Crimean war, we believe) has been the scene of considerable gaiety during the past week, and for the first time in her existence has been lighted throughout by electric lights. The occasion of this gaiety has been the giving of a series of theatrical performances by the members of the above corps. On arriving on board we were astonished to find how dexterously the main deck had been transformed into a temporary theatre, prepared, as we were, for an exhibition of some of the proverbial neathandedness of "Jack." The auditorium, if we may so call it, was lighted by a centre pendant containing six 10 candle-power Swan lamps, and another ornamental pendant of extremely handsome appearance. It consisted of a frosted glass globe of the same shape and size as an ostrich's egg, inside which a lamp or lamps were placed; the peculiarity of the globe consists in the fact that there is no brass or metal work about it at all, and it is simply enclosed by silken network, which terminates in a flexible suspension cord, inside which the leads are hidden. The glass globe takes to pieces when it is required to withdraw the lamp. This ornament is due to Mr. Vanderweyde, of Regent-street, W., and is intended as an imitation of the ostrich eggs so often to be seen hanging in the mosques of the East, where they are an object of veneration. It is very effective as a pendant, and would lend itself readily to the decoration of interiors. Two or three single lamps were distributed about the deck, at the refreshment bar, and elsewhere, in the form of table lamps, and so on, all of them having switches by means of which they could be readily turned on or off, as required. The stage was illuminated by footlights, and also by another row of lights placed some distance back, so as to throw their light on the actors from above, whilst one or two were utilised at the side to give light to the stage carpenters, &c. The total number of lights employed was 40, all Swan's, of 10 candle-power. They were fitted up and the whole arrangements designed and carried out by Chief Petty Officer Wharton, of Messrs. Laing, White, and Wharton, of Holborn-viaduct, agents for the Swan United Electric Light Company, to whom the credit of the success attained must be accorded. As evidence of Mr. Wharton's energy and resource, we may mention that he only had the order at one p.m. on Wednesday week, and that by six p.m. on the next day the whole installation was complete and ready for running. The current was furnished by twenty-two cells supplied by the Duplex Electric Light Company, of Leicester-square, W.C., the E.M.F. of which would be about $1\frac{3}{4}$ volt each. These were placed on the upper deck, and coupled up to a switch behind the scenes in such a manner as to enable 17, 20, or 22 to be thrown into circuit, according as they were required. The footlights, the lamps in the auditorium, and the remaining lamps were also connected up to separate circuits, so as to enable Mr. Wharton to regulate them to a nicety from his post behind the scenes. The lights were all connected up in multiple arc. On the occasion of our visit the performance commenced with "Meg's Diversion," an amusing piece which was much appreciated by the audience, and concluded with a musical extravaganza under the title of "The Fifteenth Century," the original composition of two members of the corps, the words being written by Mr. C. F. Fuller, and the music by Mr. Campbell Williams. Judging from the laughter and applause which continued throughout this part of the evening, both words, music, and acting appeared to be thoroughly enjoyed, as we think they deserved to be. During the last act of "The Fifteenth Century" a ghost scene is introduced, in which the electric light did good service. At a given signal, and when the feelings of the audience have been worked up to ghostly pitch, a gong is heard to sound, out go the whole of the lights, and the audience are introduced to an unearthly-looking portrait, the head of which addresses ghostly words to the actors. A gleam of moonlight falls directly on the features, and adds to their ghastliness. It is unnecessary to say that the face of a real portrait had been cut away, and the head of a living person inserted *pro tem.*, the whole affair of the ghost being a practical joke, played by one section of the actors on the rest. The gleam of moonlight was supplied by a Swan lamp in a temporary holophote projector, with a green glass in front. The effect was capital. Throughout the evening the lamps burned as steadily as could be wished, and gave quite their full candle-power, if not more. That they were under complete control was evident from the first. Chief Petty Officer Wharton is to be congratulated on the success of his arrangements, which, considering the short time at his disposal, were excellently planned and carried out. For ourselves, we shall retain a lively recollection of the pleasure experienced on the occasion of our visit to H.M.S. "Rainbow," and of the uniform courtesy of the members of the Royal Naval Artillery Volunteers.

SOME ELECTROSTATIC & MAGNETIC RELATIONS.

BY OLIVER HEAVISIDE.

1. When we confine ourselves to a single dielectric, as air, for example, and do not take into consideration the modifications produced in the distribution of force by the presence in the electric field of dielectrics of specific capacity differing from that of the main body of the field (which amounts practically to having no variations of specific capacity unless it may be in very weak parts of the field, where no sensible effect would be produced), the relations of the principal electrostatic quantities are capable of simple expression, and of more or less easy comprehension, according to circumstances. We have in the first place the electrostatic force, which is by far the most important; and next, two auxiliary functions, the electricity and its potential.

In an electric field in equilibrium a small charged conductor in general experiences force at any place, and the electrostatic force is the force that would act upon a unit positive charge placed at the point considered and supposed not to modify the field by its presence; the ordinary electrostatic unit of electricity being so defined that two charges of amounts e_1 and e_2 at distance r apart experience a repulsion of magnitude $\frac{e_1 e_2}{r^2}$.

Electrostatic force is thus a vector, having direction as well as magnitude; and the electric field becomes completely known by following the direction of the force from point to point, thus travelling along a line of force; then doing the same for another line of force, and so on; and ultimately dividing the whole field into tubes of force, a tube being everywhere bounded by lines of force, there being no force normal to its surface (save when cut across), and such that the integral amount of force crossing any section of a tube is the same, a constant for the tube. Now these tubes are all unclosed, or start somewhere and terminate somewhere else, usually upon conductors, and at the ends of a tube is supposed to reside free electricity. According to Maxwell's remarkable theory there is a real displacement of electricity all along a tube of force, proportional in amount to the strength of force at any place, and in the same direction in general (*i.e.*, in an isotropic medium, whose specific capacity does not vary in different directions), the whole displacement across one section being the same as that across any other. If this amount be e for a certain tube, then at the commencement of the tube there is an amount e of positive, and at its end an equal amount of negative electrification, or of *free* electricity, to distinguish it from the electricity displaced in other parts of the tube, which gives no indication of its presence, for a similar reason that a uniformly magnetised magnet shows no signs of "magnetism" save at the ends of the lines of magnetisation. But in the following we shall simply refer to it as the electricity.

2. However, quite apart from this hypothesis, however probable it may be, which so neatly harmonises the equations of electro-magnetism, and may almost be considered as a truth (whose recognition was, perhaps, hindered by the absurd 4π multiplier connecting electric force and surface charge, viz.:—Surface density (or displacement) $= \frac{1}{4\pi} \times$ force $\times$ spec. capacity, which is just as reasonable as it would be to say that, in a conductor,

$$\text{current} = \frac{1}{4\pi} \times \text{E.M.F.} \times \text{conductivity}),$$

we may always determine the distribution of electricity from the convergence or divergence of the force; and from a mathematical point of view, when we are only concerned with the quantitative and directional relations, we may consider the electricity to have no other meaning than to express the amount of such divergence or convergence at any place.

Describe any closed surface, and measure the integral amount of force leaving it. This (divided by 4π) is the measure of the amount of electricity contained in the enclosed volume. Applying this to the unit volume, we see that the volume density ($\times 4\pi$) = excess of amount of force leaving over that entering the volume. If this be positive, there is evidently a divergence of force on the whole at the place considered; if negative, a convergence. Let R denote the electrostatic force, and ρ the volume density of electricity, then we may say $4\pi\rho = -$ conv. R, or, $=$ div. R, where we use conv. and div. as abbreviations to be understood as follows: In terms of the components X, Y, Z, of the force, we have

$$4\pi\rho = \left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right).$$ (Theorem I., p. 55, *ante*.) The expression on the right hand side of this equation (with the $-$ sign prefixed) Maxwell called the "convergence" of the force; it is really the integral amount of force, taken algebraically, *entering* the unit volume; but since + convergence indicates negative electricity, we may as well use the term "divergence" for the same quantity with + sign prefixed, as it appears in the above equation, in fact; thus, if the amount of divergence be positive, it indicates positive electricity. Electricity is thus a scalar (directionless) quantity of one degree lower dimensions than electrostatic force as regards length.

The other auxiliary function to R, viz., the electrostatic potential, say P, is one degree higher than R as regards length, and is such that $P = \Sigma \frac{\rho}{r}$. Divide the space where there is electricity into small parts; divide the charges in these parts by their distances from a given point, and take the sum of all the quotients; the result is the value of the potential P at the given point. Since ρ is scalar, so is P.

We have also the relation $R = \text{v.}\Sigma \frac{\rho}{r^2}$ between force and density, the summation being now of vectors drawn radially from the charges. (In v. Σ the v. is to call attention to the fact of the summation being of vectors.) Likewise there is the very important relation, $R = -\nabla P$, which translated into words says that the force is the vector, rate of fastest decrease of the potential, which we may call simply the space-variation of the potential. At any point, find which way the potential falls fastest; it is the direction of the force, and its magnitude is the rate of decrease.

Thus we have, in descending order,

Scalar. Vector. Scalar.

$$P = \Sigma \frac{\rho}{r}; \quad R = -\nabla P; \quad 4\pi\rho = \text{div. R}. \quad . \quad (1)$$

Although we have only spoken of volume density, we may easily pass to surface density by the same method of considering the amount of force leaving a closed surface, which in this case must be intersected by the electrified surface where the density is required.

3. If we compare the relations in equation (1) with the corresponding relations between A, B, and C in a current system, C being the density of current, B the magnetic force, and A the vector-potential, we observe similarities and differences. For we have

Vector. Vector. Vector.

$$A = \text{v.}\Sigma \frac{C}{r}; \quad B = \text{curl A}; \quad 4\pi C = \text{curl B} \quad . \quad . \quad . \quad (2)$$

In (2) A, B, and C are in descending order as regards length dimensions, as are P, R, and ρ in (1). Again, as P is the potential of ρ, so is A the potential of C. So far there is similarity. But whereas in (2) all the quantities are vectors, in (1) we have two scalars and a vector. Also, whilst in (2), C is derived from B in the same manner as B from A, in (1) as we pass from the vector R to the scalar ρ we have the operation divergence, and from the scalar P to the vector R the operation of space variation. The relations in (2) are thus much more uniform than in (1).

Now, as has been discussed in former articles, if we form additional auxiliaries in the series belonging to the current system, below C and above A, we have the same properties repeated. Thus, if we form the quantity D = curl C, we shall have B = vector-potential of D; just as (4π) C = curl B and A = vector-potential of C. And if we form the quantity A_0 = vector-potential of B, A_0 being thus one degree above A, we shall have A = curl A_0 (with a 4π factor). And we may get rid of the remaining irregularity of appearance

Digitized by Google

of 4π, and make the relations uniform all along the series, by making the potential of a quantity $x = \Sigma\frac{x}{4\pi r}$ instead of $\Sigma\frac{x}{r}$; which in our present case amounts to making the integral amount of force emanating from a magnetic pole of strength m numerically equal to m.

4. What are now the corresponding properties in the series P, R, and ρ, when we form auxiliaries, one below ρ, another above P? Their existence is somewhat masked by the want of uniformity in (1), but they exist nevertheless.

In the first place, form the vector function R_0 one degree above P as regards length dimensions, such that $R_0 = \Sigma\frac{R}{r}$. Then we shall have the following relation between R_0 and P, viz., $4\pi P = \text{div. } R_0$; or, in words: The electrostatic potential ($\times 4\pi$) equals the divergence of the vector-potential of the electrostatic force.

Analytically, if the components of R_0 are X_0, Y_0, Z_0, we have by the definition of R_0 above

$$X_0 = \iiint\frac{X}{r}dV; \quad Y_0 = \iiint\frac{Y}{r}dV; \quad Z_0 = \iiint\frac{Z}{r}dV; \quad (3)$$

dV representing the element of volume. Therefore, by the definition of divergence, and by (3) div.

$$R_0 = \frac{dX_0}{dx} + \frac{dY_0}{dy} + \frac{dZ_0}{dz} = -\iiint\left(X\frac{dr^{-1}}{dx} + Y\frac{dr^{-1}}{dy} + Z\frac{dr^{-1}}{dz}\right)dV,$$

where we introduce the $-$ sign on transfering the place of differentiations from the point where R_0 is measured to dV itself, at the other end of r. Hence, by integrating by parts,

$$\text{div. } R_0 = -\iint\frac{R_n}{r}dS + \iiint\frac{1}{r}\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right)dV;$$

where R_n is the outward normal component of R at the bounding surface; or

$$\text{div. } R_0 = 4\pi\iint\frac{\sigma}{r}dS + 4\pi\iiint\frac{\rho}{r}dV = 4\pi P,$$

as was to be shown, σ and ρ representing the surface and volume densities of electricity.

5. In the next place, form R_1, a vector representing the space variation of ρ, or $R_1 = -\nabla\rho$; R_1 thus bearing the same relation to ρ as R to P, and inquire what relation R_1 bears to R. The answer is, $R = \text{v.}\,\Sigma\frac{R_1}{r}$, or in words: The electrostatic force is the vector-potential of the space variation of the electric density.

Take one component of R at a time. For the x-component X we have

$$X = -\frac{dP}{dx} = -\frac{d}{dx}\iiint\frac{\rho}{r}dV = \iiint\rho\frac{dr^{-1}}{dx}dV$$

where we originally perform the differentiation at the point to which X belongs, and then, in the last integral, transfer it to dV. Hence, by "parts" integration

$$X = \iint\frac{l\rho}{r}dS - \iiint\frac{1}{r}\frac{d\rho}{dx}dV, \quad . \quad . \quad . \quad (4)$$

where dS is an element of the bounding surface, and l the cosine of the angle between the normal outward and the x-axis. Disregarding the surface-integral, by extending the volume-integration over all space, and writing X_1, Y_1, Z_1, for the components of R_1, we have, by (4), and remembering that $X_1 = -\frac{d\rho}{dx}$, &c.

$$X = \iiint\frac{X_1}{r}dV; \quad Y = \iiint\frac{Y_1}{r}dV; \quad Z = \iiint\frac{Z_1}{r}dV.$$

Hence, by compounding the three left-hand members to form R, and X_1, Y_1, Z_1, to form R_1, we obtain simply $R = \text{v.}\,\Sigma\frac{R_1}{r}$, the required result.

(TO BE CONTINUED.)

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XIX.

Another way of taking the test for insulation resistance by loss of charge is preferred by some electricians, and a comparison of the two methods will show that there is much to be said in its favour. The fall of potential is measured in both cases—that is, the potential of the cable charge, after certain periods of leakage, is observed by the deflections arising from the discharges taken at the several intervals; but in the form of test now to be briefly considered a condenser is used for assisting in this purpose, whereas, as we have seen in the last number, the cable was discharged directly through the galvanometer without any other appliance. By this means it is thought that an advantage is gained in the fact that we are enabled to obtain the consecutive discharges without charging the cable more than once for all, and, therefore, that we can note the diminished potential, minute after minute, without any risk of want of uniformity in the observations. Each of these is the result of the regular fall of potential from one full charge. The cable is thus tested under conditions most favourable to the absence of change, and, moreover, the operation is much more quickly performed. With the condenser the test can be taken either with or without repetition of charge, but without condenser every discharge is the result of a fresh charge, and even if the cable were not in any way affected the battery is liable to variation, though it may be, perhaps, of small amount. The principle is exactly the same in both methods, and the deflections that are produced cannot but be considered equally true, since, if the cable must be fairly put to earth after each discharge, as we have shown in our account of the discharge test, the condenser in the other case must be as carefully discharged between every two observations. At any rate, in both cases this point is always attended to—it is, probably, of less consequence, after all, for the cable than for the condenser.

The test now before us is simple enough. The cable is charged from the battery for ten seconds, and the full charge is at once caused to pass to the condenser, and is thence discharged through the galvanometer, giving the deflection for full potential. The battery is now disconnected from the cable, and the latter commences to leak, as before described. After one minute the charge (or, rather, a portion of it) as then existing is passed into the condenser and a second deflection is taken, and the operation repeated at the necessary intervals. Now, when a cable (or condenser) is charged and then brought into communication with another condenser, the charge is distributed between them in the ratio of their several capacities, but both are charged to the same potential, though they may be of very different capacities; so that, if the cable be of much greater capacity than the condenser, a much larger quantity of the charge remains in it than can pass to the latter. If they were equal in capacity half only of the charge could pass, and thus, as whatever be the quantities, still the potential is the same, it is not necessary to recharge the cable between the observations. The object of this and the former test is to obtain a comparison or ratio of the deflections representing the potential at the time. It may be remembered that in the first of these tests the deflections represented the potential and the actual quantity in the cable at the particular moment when discharged; in the second (the present test) they also represent the potential, but a portion only of the charge remaining in the cable. The effect in either case is the same as that which would be produced by a constant current at a given potential.

The connections for the present form of test are shown in Fig. 41. The various keys, &c., are now so familiar that it is unnecessary to indicate separate parts by letters. They are accordingly omitted where not absolutely essential. In this figure the shunt has been accidently left out; its place, of course, is well known to the reader. The instructions given in the last number for taking the discharge test will require but little variation here. The battery key will not, however, be clamped down, but merely depressed; first, when taking

Digitized by Google

the full discharge, and again once for all when charging previous to the leakage of the cable, although it is not absolutely necessary to charge more than once, and take the full discharge and the others consecutively. When the minutes severally expire, the Lambert key comes into play, and the same carefulness as suggested in the previous discharge test is necessary, namely, not to confuse the contacts in charging and discharging the condenser. The cable side of the key is first touched down and released, and the other immediately depressed; the condenser must receive the charge at the cable potential exactly at the minute, and must be discharged without allowing time for any variation in itself. It is then proper to short circuit the condenser by its plug until the next minute has nearly expired. The object, of course, is apparent. The formula is worked out as before.

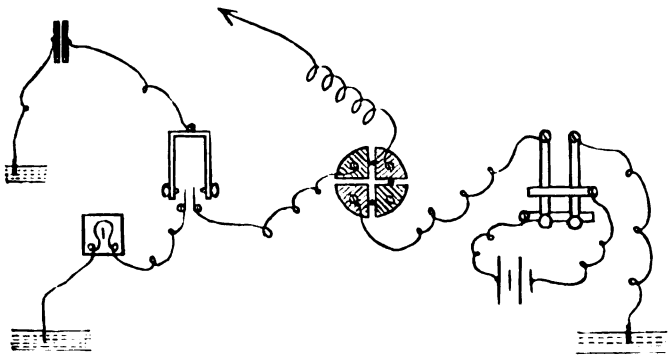

FIG. 41.—Insulation resistance Discharge test with Condenser.

We have now to show how the insulation resistance test is taken with the electrometer, and although it is not so generally employed as those already explained, it must be acknowledged to be more interesting, for the reason that the fall of potential is continuously observed and not merely determinable at certain intervals, the quadrants of the electrometer accurately representing the condition of the cable at any time during the operation. The principle of the use of this instrument has been fully considered in an early number of this series, and it is important that the practical execution of the test should be familiar to the student since it is sometimes suddenly called for, and there is but little opportunity for mastering its details in some testing rooms. We give a diagram of the connections for one form of test in this number. In Fig. 42 the same principle is illustrated as that involved in the figure given in the earlier number just mentioned. There is another form of this test to be explained later—a variation involving reversed charges. It is a very delicate one, and one by which a minute fault that has escaped discovery in the course of other forms has in some instances been proved to exist in a section of cable. The connections in our figure are here arranged as simply as possible, and we can conveniently test two or even three sections at the same time, which is sometimes very useful. There may be a dozen machines at work and half a dozen lengths besides in the tanks, the latter being sections previously run

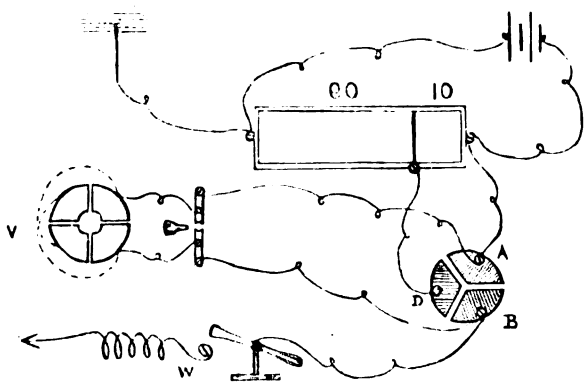

FIG. 42.—Insulation resistance test with Electrometer.

through the machines, and which are tested, perhaps, three or four times a week. It is seen on glancing at the figure that a high resistance is inserted between the poles of the battery; this may be a slide resistance of 100,000 units, and answers, besides other purposes, that of enabling us to have a practically wide range for the deflections, an object secured by a device of Professor Fleeming Jenkin, and which is called an "Inferred Zero." This device is referred to in other publications as being achieved by a somewhat different method from that explained here, but the result is the same. It will be remembered that in a recent galvanometer test we found it necessary to extend the range on the scale there used so as to get as large a deflection as possible. But the zero on that scale was in the centre, and in the electrometer scale it is at the end, so that no further extension can be made. Instead, then, of lengthening out the scale, an imaginary or inferred zero is obtained by taking a deflection from the electrometer with a potential equal to 1-10th of the full battery potential and multiplying the figure by 10. For example, a deflection of 500 would give us 5,000 as our zero or starting point, the value representing the full potential to which all other deflections are to be related or compared. It will be seen at once that the larger the deflections are the greater must be the value of any difference between them; and as we are to observe the loss of charge, it is a point of much importance to have the proportions as large as possible, since the fall of potential is comparatively slow.

The object is arrived at by the following arrangement, which will be understood by inspecting the diagram. We have here a plan of the connections for testing with one current only, as in the earlier number. Similarly also one pair of quadrants is to be joined to the cable, and the other to the battery or earth as a standard for comparison of potentials. The resistance-box contains 100,000 units, and we have supposed the 100 coils, each of 1,000 units, to be divided in two portions, the one having 10,000, and the other 90,000. At one end of the box we have one battery pole attached, at the other end the other battery pole and also an earth wire putting both battery and box to earth. Following the conditions governing the current the potential will be that of the whole battery, or "full" at the top end, and will fall regularly down through the equal coils in the resistance-box to *nil* or zero at the end which is to earth. Therefore, at a point such as that between the partitions, where 90,000 are shown separate from the other 10 the potential will be 9-10ths of the full potential, or that where the lead comes from the battery. If we call the full potential 100,000, that at the point where the other lead joins will be 90,000. By following the connections in the figure, it is seen that by means of the three-way piece or commutator either of the leads from the resistance-box and battery can be made to connect with the quadrants of the electrometer V. The dotted lines are intended to represent the wires, which join the quadrants in two separate pairs. If we insert a plug between D and B in the commutator, then it is seen that one pair of quadrants connects with the battery lead through A, and the other pair is joined to the lead through D. The first pair will be charged to the full potential, and the other pair will take up 9-10ths of the full charge. The student knows that if both pairs of quadrants were charged to the same potential there would be no deflection of the aluminium needle. Again, if one pair had been charged to full potential, and the other pair were to earth, the deflection would be much too great to be of any use; it was, therefore, necessary to have a readable deflection which should be a certain definite part or proportion of the value for full potential, that we might have practically a wide range of scale and ample deflections for relative comparison. Now we have one pair of quadrants at full potential, say valued as 100,000, and the other at a potential of value 90,000. The difference of potential of the two opposing pairs is 1-10th of the whole battery power; and assuming the cells to number 100, and to be all alike, we may say that we have the deflection from 10 cells, and multiplying this by 10, the working or inferred zero is obtained.

We see from the connections that the battery is permanently joined to one pair of quadrants (through A), and that if the short circuit plug were inserted both pairs would be

Digitized by Google

equally charged. If a plug were placed between A and B the same thing is achieved, as the one pair would be charged from A, and the other from B, through A. We only intend the short-circuit plug for general use, and in taking the test shall not employ it. We now suppose the inferred zero to have been found, and if the deflection were 500, it is 5,000. The plug will have been removed from between D and B, and will be inserted between A and B. The battery is now connected to both pairs of quadrants, and also to the distributor, which is ready to be turned on to the cable terminal at W. Having a good seconds watch before us, we wait till the hand points to 45 seconds, and at this instant turn on the distributor to the terminal. The cable now shares with the two pairs of quadrants in the charge from the 100 cells, and will be charged to the same potential. At the end of 15 seconds we remove the plug in the commutator, and thus separate the cable and one pair from the battery, leaving the standard pair still under charge. The former and the cable being both connected together must remain at the same potential, the one as the other, and as the cable gradually loses its charge, so does the pair of quadrants attached to it, and consequently the needle deflecting causes the spot of light to pass down the scale. We should have said that the spot is arranged to be at its starting point or place of rest when both pairs of quadrants are equally charged, this point being at 0 at the near extremity of the scale. The inferred zero is also obtained from this point, and when we called this zero a starting point we referred only to its value as a figure to calculate from. If the insulation of the cable is good, as it ought to be, the spot will now travel very slowly; but, if not, it travels quickly, and, perhaps, with jerks. But, supposing all to be well, we permit the cable to leak for 90 seconds and then read the number of divisions shown by the deflection, let us suppose 125. This figure is recorded, and after another 30 seconds we take a reading, say, 175. We have now got our two readings, and the test, in this case called a two minute one, is finished. We therefore turn off the distributor from the cable and short-circuit the electrometer by inserting the proper plug. The two pairs of quadrants are thus maintained at the same potential, and the spot returns to zero. If the short circuit is made with the plug in the commutator, care must be taken that the distributor be turned off first, or the cable will receive a fresh charge to no purpose. In comparing this test with those taken with the galvanometer, the student will observe that the times of observation or the intervals are not the same, but he will see that the same object is attained, and the following explanation will be of service to him :—

The first reading just taken was 125. Now, this shows that out of 5,000 divisions, which really represent the full charge of the cable before leakage, 125 have been counted off; therefore, the charge remaining at the time of reading is 5,000 — 125, or 4,875. This value is that which stands for the first of two fixed boundaries between which we are to measure the rate of leakage. The second reading was 175, and subtracting this from the inferred zero, or 5,000, we have 4,825 as the second fixed boundary separated from the first by an interval of 30 seconds. Here we have the amount of charge left in the cable at two separate periods, so that the ratio or relative proportion of these two values gives us, or is the proportional amount of leakage during the half minute, then $\frac{4875}{4825}$ taken as a ratio shows how much greater is the charge at the commencement of the 30 seconds than at its expiration. Consequently, by inverse reasoning, it shows how much of the charge at any time after beginning to leak has escaped during 30 seconds. To make this plainer, suppose that from a vessel of water holding 1,000 quarts a quantity is drawn off at two periods 30 seconds apart, and say that we first let it escape for 90 seconds, and then find that 200 quarts had gone. There are thus 800 left, and, letting the water run for 30 seconds, let us suppose that 600 quarts in all have escaped, there are consequently 400 quarts left, and 400 ran out during this half minute. Therefore $\frac{800}{400}$, or 2, is the value or figure representing how much the quantity in the vessel at the beginning of 30 seconds exceeded that left at the close, that is, in this case twice. Conversely, half the quantity in the vessel escaped in 30 seconds. We see that the ratio $\frac{800}{400}$ measures the leakage in 30 seconds, and the power to resist leakage (so to speak) is only as 1 : 2, the power to leak is to the resistance as 2 : 1. We have not intended to compare the escape in this example with the fall of charge in a cable in every respect, on several grounds. Our object is simply to establish the fact that the ratio represents the rate of leakage, and we see that the action is an exemplification of compound interest.

From the data which we have now got, and following the explanations given in the last number, the results are obtained. Referring to these remarks on the formula for loss of charge, a word on the fraction given as $\frac{P}{p}$ may be useful. This ratio in the galvanometer tests is that of the deflections, and in the electrometer test is that of the values got by subtracting the deflections from the inferred zero. We observe then, that as the first reading's difference from inferred zero : the second ditto :: the charge of the cable at any potential to the loss in the half minute, and so the remaining value. Conversely, as the second difference : the first :: the loss per half minute, or the remaining charge, : the charge of the cable. Therefore $\frac{P}{p}$ is the ratio of charge to loss per half minute. From this it follows that the greater $\frac{P}{p}$ comes out the worse is the insulation of the cable, P and p being regarded as values. Thus if the ratio were $\frac{8}{4}$ the value of P as compared with p is 2; but if it were $\frac{8}{2}$ this figure becomes 4, and the cable appears as affording a resistance to leakage less in the second case by one half. We are not to regard p, or the denominator of the fraction, as directly representing the leakage, but rather as resistance to leakage, and the whole fraction is to be held as a "bad quality." This test is totally irrespective of the entire length of the cable—the conditions are those of time, capacity, material, &c., and certainly of length, but in proportion only. Of two cables of the same length one might give a larger value for the fraction than the other; it would be a worse cable, that is, if made of exactly the same materials, and altogether uniform with it.

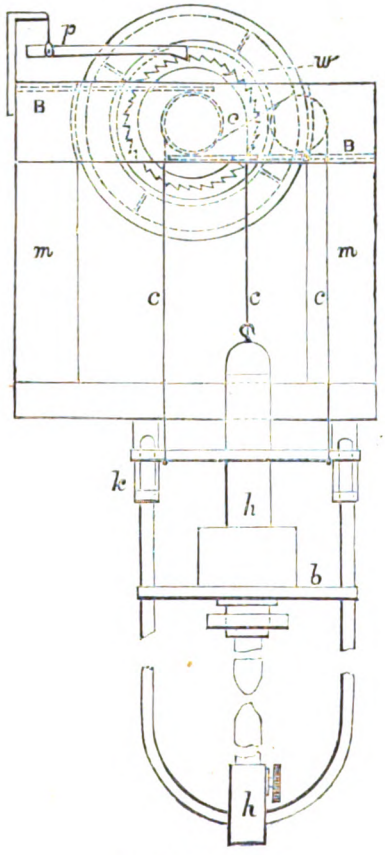
GRAY'S ARC LAMP.

This lamp, which is the joint invention of Mr. A. Gray, M.A., F.R.S.E., Chief Assistant to the Professor of Natural Philosophy in the University of Glasgow, and Mr. Thomas Gray, B.Sc., F.R.S.E., and is made by Mr. James White, Glasgow, possesses some points of novelty which may be interesting to the readers of *The Electrician*. It belongs to that class in which the carbons are made to approach each other by the action of gravity, and are separated by an electro-magnetic controlling apparatus. The upper carbon holder is made sufficiently massive to allow the gravitational action to be but little affected by the change of weight of the carbons themselves. When the lamp is one designed for constant focus, the lower carbon holder is arranged so as to be raised through the proper relative distance by the descent of the upper carbon holder. The motion of the carbons is regulated according to the strength of the current flowing in the arc by a convenient form of electro-magnetic controlling apparatus.

So far the principle of the lamp is similar to that of many others. One main feature of novelty, however, is the employment, in combination with the electro-magnetic appliances, of a hollow drum or ring divided into compartments by partitions, each of which is pierced by one or more orifices pro-

Digitized by Google

perly placed. The space within the drum, or its equivalent, is partially filled with a suitable liquid, the action of which is to render steady and gradual the movement of the carbons either towards or from one another. This action is very simple. The drum is mounted so that the motion of the upper carbon holder upwards or downwards turns it round on its axis. The liquid is carried round with the drum, and acquires a difference of levels on the two sides, in virtue of which it applies a couple opposing the rotation of the drum on its axis. The couple increases as the angle through which the drum is turned is increased, until, if the drum is of sufficient dimensions, or the liquid sufficiently dense, the couple applied by the liquid just balances that applied by the motor mechanism of the lamp. After equilibrium has been thus obtained the drum will turn round on its axis, in obedience to the couple applied by the lamp mechanism, with a slow motion depending on the rate of loss of head of the liquid in the drum, in consequence of its flow through the orifices. Thus, in Messrs. Gray's lamp, the flow of the carbons towards one another in normal circumstances takes place with a slow,



Gray's Arc Lamp.

uniform motion, the lamp adjusting itself so that the couple applied by the gravity of the upper carbon and its holder preponderates just so much over the retarding couple applied by the electro-magnetic controller that the carbons are fed as they are consumed at the proper rate, under the regulating influence of a small head of liquid in the drum. If, however, any change takes place, in virtue of which the turning motive on the drum in one direction or the other tends to increase, the motion is at once moderated by the regulating action of the liquid, and the steady and gradual feed of the carbons is restored before any perceptible disturbance of the light has taken place.

The form which the regulating mechanism of this lamp has now taken is illustrated in the sketch, which shows diagrammatically the arrangement. The electro-magnetic controlling apparatus is a small Gramme motor, the magnets *m m* and armature *r* of which are wound with coils of thick wire, which are joined in series with the carbons. In order that the lamp may be burned with different strengths of current a coil of thin wire is also wound on each of the magnets and placed as a shunt on the arc in the usual manner, so that its magnetising effect is opposed to that of the thick wire coil. The lamp is thus suitable for use in a circuit in which two or more arc lamps are burning in series. For, assuming that the magnetisation of the magnets is proportional to the current, we have for the equilibrium of the carbons the equation,

$$A C^2 - B C E = L,$$

where A and B are constants, C the current strength in the thick wire coils, E the difference of potentials between the two ends of the thin wire coils of the magnet, and L the couple due to gravity tending to turn the armature, so as to bring the carbons together. If a sudden change in the current strength C takes place, due, say, to the coming into contact of the carbons of one of the lamps, the others adjust themselves so that the difference of the quantities on the left hand side of the equation above is still equal to L; and beyond, perhaps, a brightening of the lamps still burning, no disturbance is caused by the extinction of one of the arcs in consequence of the carbons coming together and ceasing to separate. A simple electro-magnetic arrangement, not shown in the drawing, acts, if the carbons by any accident cease to come together, and cuts out the lamp, inserting at the same time a resistance equal to the average resistance of the lamp, so that other lamps in the circuit may continue to burn as before.

The iron ring *r*, forming core of ring of the regulating motor, is made hollow, as shown by the dotted circles, and is divided into communicating compartments by partitions, so as to be used instead of the hollow drum described above. The hollow space is partially filled with mercury. By this arrangement the use of a separate drum is avoided, and it is more effective and not less compact than the obvious plan of a hollow cylinder contained within the Gramme ring. The current is sent through the ring by means of brushes, B B, which run on a commutator, C, on the spindle of the ring of the motor in the usual manner. Each of these brushes is formed of a large number of strips of very thin copper placed one above the other. Several layers of the strips next the commutator bars are slit at the bearing part into a fringe, so as to give, as it were, a soft pad bearing on the commutator. The spindle of the ring carries at the other end a set of three pulleys, two of which have half the diameter of the third, and are placed one on each side of the larger pulley. Round these are wound in the proper directions cords, *c c c*, made of fine copper wire, which carry the upper and lower carbon holders *h h*, so that while the upper or positive carbon descends a certain distance, the lower carbon holder ascends through half that distance. The rods of the lower carbon holder slide loosely through guides formed by holes in the ends of a crossbar, *b*, carried by the upper carbon holder, but insulated from it, and two brackets, *k k*, fixed to the framework of the lamp. It is, of course, unnecessary for some purposes that the lower carbon holder should be movable, and in such cases the upper carbon holder only is suspended.

The action of the lamp is as follows:—When no current is passing through it, the carbons are held with their points pressed together by the action of gravity. When the current is sent through the magnets and armature of the motor, the armature revolves in the direction tending to lift the upper carbon holder, and thus separates the carbons and establishes the arc. This initial motion of the carbons is regulated by the action of the mercury in the hollow ring; and the feed of the carbons is kept up continuously thereafter by the gravity of the upper carbon holder, resisted by that of the lower carbon holder and the electro-magnetic action of the motor regulated by the liquid in the ring.

To prevent the motor, when striking the arc, or when a sudden increase takes place in the current flowing through the lamp, from producing too great a separation of the carbons, the ratchet wheel *w* is fixed behind the pulleys on the spindle of the ring. A pawl, *p*, suspended by a thin piece of very flexible metal from a fixed support is free to move in the plane of the wheel, and rests by its own weight on the ratchet. When the carbons are separated the pawl is carried to the left by the ratchet until by coming against a stop it is prevented from going further, and thus stops the

Digitized by Google

rotation of the armature in the direction to separate the carbons. This initial separation is arranged to be greater than the normal length of the arc, and the continuous regulating action comes thus into play at once. This ratchet is always convenient, as it allows a smaller mercury regulator to be used, but it is more especially wanted when several lamps are burnt in series.

A lamp of the same type, except that the regulator containing mercury is made of boxwood and placed on the same axis as and within the ring of the motor, has been supplied to Sir William Thomson for laboratory and other use. On the occasion of the installation of Mr. Bright a few days ago as Lord Rector of the University of Glasgow, it was temporarily suspended in the Professors' Court and placed in the circuit of the dynamo by which Sir William's house in the University is lighted. The light was beautifully clear and steady, and was not at all affected by the putting on and off of several incandescent lights arranged in parallel circuit with the lamp. A trial of it in the new Bute Hall of the University proved that this form of lamp, because of its great steadiness and silent action, is extremely well adapted for the lighting of large public buildings. This great hall is about 80ft. from floor to ceiling, 144ft. in length, and 68ft. in width. The single lamp hung from the roof at a height of about 50ft. from the floor lighted brilliantly every part of this large building (except, of course, where shadows were thrown by pillars under galleries) at an expenditure of about one horse-power in the lamp itself.

The lamp was also exhibited at a private entertainment given by Sir William Thomson to his laboratory corps and to other students of the Natural Philosophy Class. It was hung from the staircase above the entrance hall of Sir William's house, and proved itself, by its clear and steady light, admirably adapted for lighting the halls and passages, and even the large rooms of a private house.

STUDENTS' COLUMNS.

CITY AND GUILDS EXAMINATIONS.

The solutions in this number are solutions to some of the "*Honours*" questions in the paper hitherto considered, by E. C. Rimington, Esq. (School of Electrical Engineering), 12, Princes-street, Regent-street.

20. Explain how the very high potential necessary for obtaining economic electric transmission of power can be practically employed by the use of secondary batteries.

Ans. By employing this high potential to charge secondary batteries, arranged in series, so that their back E.M.F. is nearly equal to that at the ends of the line. When charged, the batteries are disconnected and arranged, a certain number in series, and a certain number in multiple arc, so as to obtain the E.M.F. required to work the lamps or motors, and are thus discharged, fresh batteries being put in their places to be charged.

21. What are the advantages of electric railways over the present system of railway propulsion?

Ans. The chief advantage of electric railways over ordinary locomotives is to be derived from the fact that very large stationary engines can be worked with far greater economy as regards fuel than locomotives can be, because, in the case of the latter, economy in fuel has to be sacrificed to a very great extent to size and lightness in construction. Another advantage is as regards weight, as the motor required to propel a railway carriage may be of small dimensions and weight. Further, the permanent way and bridges, &c., may be lighter and, therefore, cheaper.

Errata.—In answer to question (16), page 350

$$\therefore \frac{w}{e} = \frac{E\,(E - e)}{746\,R} \text{ should read } \therefore \frac{w\,E}{e} = \frac{E\,(E-e)}{746\,R},$$

and near the bottom of the page

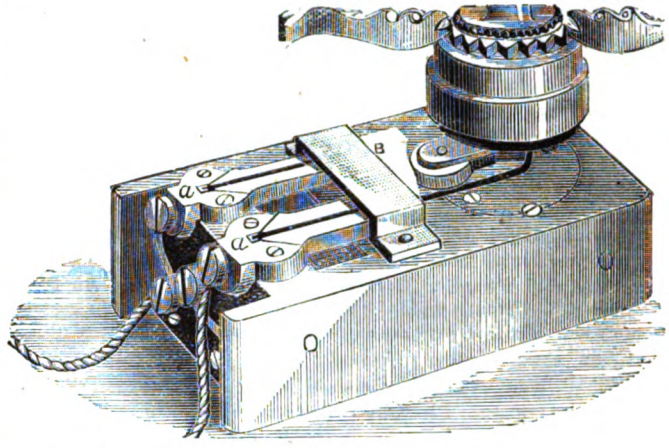
$$H = \frac{w\,(E \mp \sqrt{E^2 - 2984\,w\,R})^2}{2984}$$

should be

$$H = \frac{w\,(E \mp \sqrt{E^2 - 2984\,w\,R})^2}{2984\,R}.$$

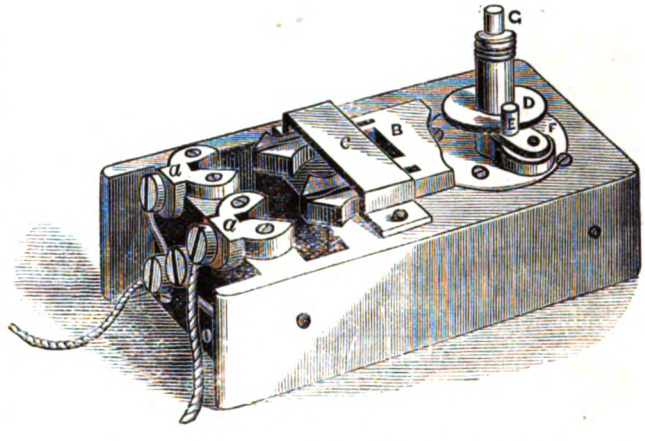
BAYLEY'S PATENT SWITCH FOR ELECTRIC LIGHT AND OTHER PURPOSES.

This switch consists of two strong gun metal segment terminals with V-shaped receiving sections, *a a* (Fig. 1), also a bolt, B, of gun metal, the contact faces of which are carefully shaped and fitted to the contact faces of the terminals. The



Bayley's Switch, with outer case removed.—Circuit Closed.

contact portions of the bolt are split, and strong steel springs securely fixed in them, necessitating perfect electrical contact when the circuit is closed; C is a guide bridge, guiding the bolt B home; G is a centre spindle pin, with a movable flange, D. Attached to this flange is a lever pin, E, to which is also attached a steel roller, F. On the top of G is a metal segment, with a play cavity on one side securely fixed into an insulated segment, covered with a metal cap that carries the ornamental lever handle. When the handle is turned it causes the roller to press the bolt B (Fig. 2) into contact with the terminals *a a*, the steel springs in the bolt plugs always causing good electrical contact. The drawback spring is



Bayley's Switch, showing details of handle.—Circuit Open.

buried in the insulite material, on which the whole of the work is mounted. The great advantage of this switch is that it is beyond the operator's control when shutting off the lights to make arc, or, rather, the arc is reduced to a minimum. The moment the roller passes the centre of the bolt it flies completely out of circuit, its arcing is thereby reduced to the lowest possible point. A switch sent us for examination was designed to control from 60 to 80 lamps of 16 candles each. A safety fuse wire is inserted, S shape, between two terminals, as shown. These switches can be made in all sizes and various ornamental covers. The workmanship in the one under our notice is excellent. The switch is enclosed in a neat brass case.

THE ELECTRICIAN.

TO CORRESPONDENTS.

All letters intended for insertion in THE ELECTRICIAN, *or containing questions, must be accompanied by the name and address of the writer, not necessarily for publication, but as a proof of good faith. No notice whatever will be taken of anonymous communications.*

All communications to be addressed to 396, *Strand, London, W.C.*

We cannot undertake to return drawings or manuscripts, and must, therefore, request Correspondents to keep copies.

ANSWERS TO CORRESPONDENTS.

LEIDHBOURNE.—*We have no objection to publish your letter. We think the suggestion would hardly meet with general response. If we mistake not the idea has been mooted several times, and was found to be impracticable. Our opinion is, perhaps, not worth much; but it is that there does not exist in your profession a sufficient number of able writers, even if there were readers to be found, to command success.*

A WELL WISHER.—*The name you mention is, we think, not Albert but Albright, and the Company the Swan Company, whose address is St. Mildred's-court, Poultry, E.C. It would be preferable for you to write to that address than for us to insert your letter.*

C. A. S.—*You had better communicate with Messrs. Elliott Brothers,* 449, *Strand, W.C.*

TELEGRAPH TARIFFS.

In the course of the speech with which he introduced the Budget Mr. Childers announced that he had set aside £170,000 out of this year's surplus to meet the deficit consequent upon the adoption of sixpenny telegrams. Following close on the heels of the peculiar division which took place the week before, and coupled with his own expression of opinion on that occasion, the announcement can only be regarded as another example of immediate and unconditional surrender to clamour—the clamour in this instance, as we pointed out last week, being of the most selfish and least public-spirited sort. The incident is highly significant seeing that the money cannot possibly be needed for the present year. There can be no sixpenny telegrams until the Telegraph Department is able to deal with them—not until additional wires, more apparatus, and increased staff are ready for use. Money will be needed, but it will be in the shape of additional capital, not to meet a deficit in revenue. It has been the fashion of late years to overtax and underestimate in order to create the semblance of a surplus at the end of a financial year. The new Chancellor of the Exchequer seems to be following that very effective though somewhat oppressive line of policy. He will probably have his £170,000 intact at the end of the year; meanwhile, the taxpayer has to pay for its being "set aside" in anticipation of a deficit that is not likely to occur. Members "below the gangway" applaud, however, and it is a great point to get applause from that quarter; so we are to have sixpenny telegrams, and a consequent cessation of complaints against the Treasury.

That being the case, somebody will have to determine what the sixpenny telegram is to be. In this relation we should have liked to know on what bases the calculations referred to by the Postmaster-General were made by those officials whose estimates of deficiency consequent on a reduced tariff differed so very widely. Nearly everything depends on the size of the telegram. Public opinion will no doubt be sounded during the next few months before this point is decided. At present we can only be certain on two points—first, that there is some conflict of opinion between the parties who are likely to be the final arbiters inside and outside the House of Commons; but, secondly, that the sum named above is in any case supposed to be sufficient to cover the first year's loss. That sum being fixed upon, it is probable the tariff finally recommended by the Telegraph Department will be such as they anticipate will be justified by the provision. This is unfortunate, for it may prevent the tariff being framed on equitable and common-sense principles. Nevertheless, while the subject is fresh in the public mind we will venture to offer a few remarks on the sound principles which ought to regulate all tariffs.

First, as to uniformity. This is purely a matter of public convenience, and cannot apply to countries of any considerable area. What seems just and natural for small kingdoms like Belgium, Holland, and even Great Britain would be absurd, say, for the Russian dominions. Conversely, the argument for lower tariffs on town telegrams holds good where the national territory is large, but the towns comparatively small. Were it not for London being practically a county in itself, indeed for telegraphic purposes as extensive as some European States, a local tariff might be practicable in this country. But we must look at the facts, and the facts are against any generalisation applicable to all countries and towns alike.

These remarks apply equally to the word tariff. Its merit as a uniform system extends so far, and no farther, than the geographical facts will permit. It is roughly based on distance, and, to the extent that it taxes the sender for the exact number of words he requires to be signalled, it is equitable; but it would be easy to point to anomalies which, on the assumption that uniformity is the public's by right, are quite indefensible. The telegraphing public have a right to just so much simplicity and uniformity as the circumstances will warrant, and no more. The word tariff for international telegraphy happens to be workable on other grounds. The addresses are very short, for the simple reason that international telegraphy is chiefly confined to the commercial community, whose places of business are well known. For inland telegraphy this word tariff, which is theoretically the most equitable, would be unfair to the general public, whose addresses are necessarily longer than those of business men. It would lead to curtailment of addresses in order to save

Digitized by Google

expense, if the telegram, as a whole, were charged by the word; and it would also put the carriers to a good deal of extra trouble and expense for delivery.

The uniformity, therefore, at once practicable and equitable for a country like this, would consist of a fixed price for any number of words not exceeding a certain limit. Its next stage would depend so much upon the initial limit and upon the mode of counting, that we need not discuss it until these points are settled. The main thing to be done is to fix the limit; but this cannot be fixed until the vexed question of free addresses is disposed of. If the agitators for cheap telegrams had been sincere or disinterested they would have demolished the existing system long ago. Of all the anomalies in the world-wide range of telegraphy, none is so monstrous and so utterly indefensible as that which Mr. Fawcett has mildly described as "wasteful." He might have said ruinous without much exaggeration. It concedes to the public the right to send any number of words for nothing, providing they come under the heading of addresses. A great opportunity of remedying this abuse was lost when the telegraphs were acquired by the State; now again an opportunity has arisen, and if advantage be not taken of it, there will never occur another. We shall probably return to the discussion of this part of the question before it is finally settled; but for the present we may be content to point out to the business classes, whom, after all, this reduction of tariff will chiefly affect, that their interests are decidedly threatened by the continuance of free addresses. The initial limit for the chargeable text must necessarily be low if addresses are to go free; if they were charged for, as they ought to be, the text could be proportionately expanded, and the text is the main thing for commercial men.

We shall be agreeably surprised if the price for Press messages under the new tariff is not made the subject of question and discussion before this Session is over. It is notorious that the Press is served on exceedingly liberal terms at present. But the Press is apt to set its own estimate upon its title to consideration, and when we see the newspapers unanimously advocating a measure the true bearings of which it is plain they know nothing about, we may safely infer that they are saying one word for the public and two for themselves. Yet there is no logical justification for treating them differently from the general public. Night messages ought by rights to be charged for at extra rates; but, if the reverse of this proposition is to hold good on the ground that, night service being unavoidable, the wires may as well be earning money, then it follows that the public as well as the Press should have the benefit of cheaper rates during the slack hours, and the rate should be substantially the same for both. This, at all events, is the equitable view to take of the case. If, in actual practice, it is found that Press telegrams are remunerative at a lower figure than are ordinary messages, then the Press is entitled to an abatement. But we fail to see how this newly-proposed reduction on public telegrams will entitle the Press to a further reduction on theirs; on the contrary, the large increase in the number of public telegrams that may be reasonably expected to be forwarded after business hours under the new tariff seems to point in the opposite direction.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 6th April, 1883, were £2,342, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

OURSELVES.

The annual social gathering of the proprietors and contributors of *The Electrician* was held at the Criterion on Monday, April 9, under the presidency of J. Pender, Esq., M.P., when an excellent dinner was provided by Messrs. Spiers and Pond. Several well-known contributors were unavoidably absent, and we missed some transatlantic friends who have in previous years favoured us with their presence. Sir J. Anderson was vice-chairman, and the following gentlemen were around the table:—W. C. Cartwright, Esq., M.P.; Mr. C. H. B. Patey, Mr. E. Graves, Mr. W. H. Preece, Mr. Albright, Mr. K. Anderson, Mr. W. W. Beaumont, Mr. Shelford Bidwell, Mr. C. H. W. Biggs, Mr. T. H. Blakesley, Mr. R. E. Crompton, Mr. Brockwell Dalton, Mr. J. J. Fahie, Mr. D. G. FitzGerald, Mr. L. Florsheim, Professor W. Garnett, Professor D. Hughes, Mr. E. H. Johnson, Mr. G. Kapp, Mr. J. Laister, Mr. J. F. Moulton, Mr. W. H. Parker, Mr. J. Pender, jun.; Mr. E. C. Rimington, Mr. H. Saunders, Mr. Willoughby Smith, Mr. J. T. Sprague, Mr. J. H. Swan, and Mr. F. C. Webb.

During the course of the evening the chairman remarked that, although this might well be termed an electrical age, he was still of opinion that the applications of electricity were only in their infancy, and from experience he could tell the scientific men present that the monied interests would always be ready and willing to hold out a helping hand towards any developments that showed great promise, and he entertained the idea that at no very remote future the Society of Telegraph Engineers ought to rank as high in the opinion of the world as the Institution of Civil Engineers does now. Sir J. Anderson, in reply to the toast of "*The Electrician*," pointed out that the intention of the proprietors of the paper was that it should be the best paper on its special subject that could be found in this or any other country.

CORRESPONDENCE.

UNIPOLAR DYNAMO MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In your issue of March 31 you gave an account of Ball's so-called "unipolar" dynamo, and also printed a report upon one of these machines now being exhibited in London.

My attention was some weeks ago drawn to this dynamo, and the conclusions I then formed are still unaltered, viz., that it had no points sufficiently good to cause an intending user of electric force or energy to buy it in preference to many other dynamos now in the market, letting alone the question of its not being as good as some others.

Most *thinking* electricians will regret that this report should have been published, as it unintentionally misleads the public, proper instruments and apparatus not having been provided, as is proved by the following quotation from the report:—

"The speed of the machine was not so regular as could have been desired, and the Morin dynamometer by which the power given to the dynamo was measured would have worked steadier had it been run quicker and with a heavier load."

I thus find some essential points unreliable by their inaccuracy when I wish to test the real value of a dynamo, viz., the relation of the amount of useful work in outer circuit to that employed in driving the dynamo.

A contemporary points out that this dynamo by this report appears to return 5 or 6 per cent. more useful work than the best of the various dynamos of the well-known maker tested by the committee at the late Electric Exhibition at Paris.

Now, as the speed and dynamometer readings were so inaccurate and irregular, these results cannot be accepted as satisfactory or accurate.

Another point. The report states 3·92 h.-p. was accounted for in the outer circuit, and, further, in the mean result,

Digitized by Google

accounted for in one lamp is 0·75 h.-p. (or, more exact, 0·74), thus giving as the mean result for the six lamps 4·48 h.-p. in the outer circuit, leaving out any work done in the connecting wires, or 0·56 h.-p. in excess of his previous total mean h.-p., viz., 3·92.

If I accept this 4·48 h.-p. as a correct mean, then the proportion of work accounted for electrically must be $\frac{4·48 + 1·35}{5·68}$ $= \frac{5·83}{5·63}$, or over cent. per cent., which is impossible, or, leaving out the odd 0·20 as sundries or inaccuracies, the only explanation can be is that no so-called Foucault's currents are produced, a point even the inventor of the dynamo will hardly claim.

I am aware in making the above remarks that the report clearly states that the figures relate to only one lamp, but inasmuch as the candle-power given is that of this lamp, the results published tend to mislead the public by inference that the other lamps are equal to this one, which cannot be, as shown. The diagram showing the winding and connection of the dynamo is incorrect, for how a north-pole piece can be produced in the centre of a covered bar when the current is flowing in the same direction in the portions on either side of the pole piece is extraordinary.

But as this may be only a draughtsman's error, I look to the theory of the neutral pole piece and the unipolarity.

Now, when the pole-piece is throwing off magnetic lines of force, these must necessarily be attracted by any stationary piece of iron near, and if this iron is neutral as far as the circulating currents in the field magnets are concerned of which it is a part, it still must have some polarity given to it by induction from being in the neighbourhood of the active armature, and when it is so induced the previous state of neutrality must be considerably modified, and the iron, now a pole piece, will, in consequence, react upon the lines of force from the other active pole piece. This neutral iron is thus converted into a *supplementary pole piece* by accident, though not design.

This *supplementary pole piece* at once cuts away the ground for calling this dynamo a unipolar one, as far as the fields are concerned, and, as far as I am informed, Mr. Ball does not claim unipolarity for his armature.

There are many other points, had I dared trespass upon your space, I should have liked to have drawn attention to, for I feel very strongly that more difficulties should not be placed in the progress of electric distribution than there are at present by the promulgation of misleading statements obtained from unsatisfactory data.

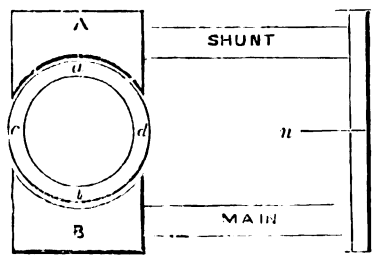
I think, therefore, that Mr. C. W. Raymond should, in the interests of Mr. Ball, at once have a fresh report made, and should before doing so see that the speed of rotation of the dynamo could be kept constant, and the dynamometer working so as to give absolutely correct results.—Yours, &c.,

E. E. A.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The recent description of Mr. Ball's dynamo machine has given rise to considerable comment as to the use of one inducing pole in magneto-electric machines, and it is somewhat surprising to learn that the capability of inducing a current under the condition is thought novel. Perhaps the false notion that in a Gramme ring the inside wires were of *nil* effect in producing electromotive force may have retarded the observation by preventing the true action (or perhaps I should say the action as *experimentally* determined) of the Gramme ring obtaining general support. If we look upon the Gramme ring as a particular form of electro-magnet a great deal of the mystery surrounding it disappears, and that this is the true function I hope the following observations, obtained in experiment, may at least help to prove. Let the diagram represent a Gramme ring revolving between the poles of an electro-magnet. In the particular case of Mr. Ball's dynamo we may remove one of these poles, because his ring is set between, say, A and the neutral line *n* of the magnetic arrangement; but I will consider the use of one pole as it occurs to a greater or less degree in my self-regulating machines, after pointing out an extension of the use of one pole.

If A be made a north pole, then *a* will become south by induction, and *b* north. *If the mass of iron in the ring is not too great and yet sufficient*, the neutral line or brush-diameter will be at *c d*. *If the mass is insufficient, or is too small in section with relation to its length (around the circle), then the points c and d will approach a.* These conditions have long been known to me experimentally. I am considering B to be removed or to be inoperative. But suppose that B as well as A be made a N pole, then *c* and *d* become south by induction, and we have to put our brushes at points intermediate to *a* and *d*, *d* and *b*, *b* and *c*, *c* and *a*, but the sign of the brush (+) is no longer alternate counted round the ring. This extension of Mr. Ball's idea has, I believe, been patented, and is no more a bi-polar machine than is that due to Mr. Ball's "unipolar."



But these induced poles are not capable, in my experience, of producing the same electromotive force, for the same speed and length of wire.

As to the question of the action of the Gramme ring, let A be a N-pole, and B a S-pole, and let the iron of the ring be separated into parts *a*, *d*, *b*, *c*, *a*, so that each part is magnetically insulate from the next parts whilst the wire is continuous—easily carried into effect by composing the ring of separable bobbins joined together with strips of brass or of iron, as may be desired, at the junctures, or as in the case of the actual experiment connected by either brass or iron bolts, the wire on the ring remaining unaltered. Now, when the brass bolts are in, there is *no* electromotive force of any practical value, but when the iron bolts are in the magnetism and the electromotive force are fully developed. Whatever may be due to the windings of the wire is purely a matter of theory, for with the same mass of iron in detached pieces in the ring, the incompletion of the electro-magnetic system (although the "magnetic screen" is still there) is productive of a *nil* inductive result. Now, whilst the brass bolts are in, if a bar magnet be approached so as to bring about a completion of the electro-magnetic system in one of the segments, *e.g.*, supposing A a N-pole, let the S-pole of the bar magnet be brought to the point between *a* and *d* corresponding to one of the separable lengths, then an appreciable E.M.F. is immediately manifest. Of course the bolts must afford a good and sufficient surface for the magnetic contact between the separable parts. I contend that if, as certainly appears, the action of the Gramme ring is mainly that of an electro-magnetic system, then the inner wire is as efficacious as the outer wire. That there *is* an E.M.F. due only to the outer wire is undoubted, but it is very small.

Mr. Oliver Heaviside, I was glad to observe in a recent number of this journal, gave his adhesion to the equal efficacy of the inner wire of the Gramme ring; and I think it can be proved also from Du Moncel's simple yet elaborate experiments.

I have remarked that the effect of using only one inducing pole has been known to me for a long time; it is one of the means by which in larger sizes of my self-regulating machines I obtain a thorough control of the circuit. From time to time I have been somewhat amused by the so-called mathematical proofs offered of the necessity of maintaining a constant electromotive force in a self-regulating system *at the terminals of the machine*. Had the worthies who are so ready to instruct us ever put their theories to the test of

Digitized by Google

practice, they would have found that it is the difference of potentials at the far end (of a multiple arc) circuit that must be maintained constant. To adopt the argument *ad hominem*, let G be the generating station, H the next house, and I further down the street:—

G . . . . H . . . . I.

Now we maintain a very constant difference of potential at G, but if H plays pranks I will know all about it. For instance, let, in a lighting circuit, H adopt his own lamps, of the same number may be, but of half the resistance of I's, then I will soon know how much a constant difference of potential at G is worth; or, to proceed to limits, let H short circuit. Then, of course, I has no current, whether of gas, water, or electricity. The practical engineer will tell us the constant head must be at the *end* of the main.

How H can be prevented taking more current than he contracts for is not the present point; but it can be done easily and without going farther than the generating machine, and I shall be glad to enter on the subject in your journal if you can find room for my remarks at a more opportune time. I was about to say that, as in the diagram above, the polarity A being provided by the shunt circuit, we can have an initial E.M.F. of any power we choose to arrange, without any influence from B (except from induction). *Now we may light a certain number of lamps, using* A *pole only as in a shunt machine;* or we may begin to pass current through B, and use the whole self-regulating system. In the first place, we start with a close approximation to a so-called "unipolar" machine, but with the advantage over a self-regulating machine with the shunt and main magnets on the same cores that the earlier lamps are better under control and are never over-forced. If the main circuit becomes of a lower resistance than is provided for in normal running the machine comes again into action with a single pole, that due to only the main circuit at the limit when the resistance is too low to maintain a charging current in the shunt-magnets. And although the main-circuit magnet is superexcited, its pole alone is acting, and the electromotive force is not increased. The range of self-regulation can be thus much extended, and render large machines as controllable as small.—Yours, &c., PAGET HIGGS.

WEDGWOOD'S TELEGRAPH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Among the early proposed electric telegraphs it appears to me that that of Ralph Wedgwood, the inventor of the carbonised manifold paper so extensively employed for copying letters, has hardly received the attention it deserves. The account of his telegraph appears at the end of a volume entitled "The Book of Remembrance," by R Wedgwood, London, 1814, and forms part of an appendix, in which he describes the carbon paper. He says:—"*The Fulguri Polygraph*, which admits of writing in several distant places at one and the same time, and by the agency of two persons only.

"This invention is founded on the capacity of electricity to produce motion in the act of acquiring an equilibrium, which motion, by the aid of machinery, is made to distribute matter at the extremities of any given course. And the matter so distributed being variously modified in correspondence with the letters of the alphabet, and communicable in rapid succession at the will of the operator, it is obvious that writing at immense distances hereby becomes practicable; and further, as lines of communication can be multiplied from any given point, and those lines affected by one and the same application of the electric matter, it is evident from hence also that *fac-similes* of a despatch, written as for instance in London, may with facility be written also in Plymouth, Dover, Hull, Leith, Liverpool, and Bristol, or any other place, by the same person, and by one and the same act. Whilst this invention proposes to remove the usual impediments and imperfections of telegraphs, it gives the rapidity of lightning to correspondence *when* and *wherever* we wish, and renders *null* the *principal disadvantages* of *distance* to *correspondents*. Independent of the advantages which this invention offers to Government, it is also susceptible of much utility to the public at large; inasmuch as the offices which might be constructed for the purposes of this invention might be let to individuals by the hour for private uses, by which means the machinery might be at all times fully occupied; and the private uses which could thus be made of this invention might be applied towards refunding the expenses of the institution, and also for increasing the revenue. Innumerable are the instances wherein such an invention may be beneficially applied in this country, more especially at a time when her distinguished situation in the political, commercial, and moral world has made her the central point of nations and the great bond of their union. To the seat of her government, therefore, it must be highly desirable to effect the *most speedy and certain communication* from every quarter of the world, whilst it would at any moment there concentrate instantaneous intelligence of the situation of each and every principal part of the nation, as well as of each and every branch of its various departments."

—Yours, &c., LATIMER CLARK.

SAFE CURRENT THROUGH COPPER WIRE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the letter of Mr. H. Cleland Heywood in the last number of *The Electrician* (page 495), on the subject of the current of electricity which may be safely transmitted through wires of various sizes, we enclose you a table of sizes and weights, calculated from the formula given, which may prove useful. We would at the same time remark that the table is intended for use in the hot climate of India, and is applicable to insulated wires, which may, as in our experiments, be surrounded by dry wood, sand, or other imperfectly conducting material. In this country similar wires, especially if exposed to radiation, might be trusted to carry considerably larger currents.

There are two clerical inaccuracies in the formulæ as given, which require correction, viz:—

$$W = w\left(\frac{m}{n}\right)\frac{4}{3} \text{ should read } W = w\left(\frac{m}{n}\right)^{\frac{4}{3}}$$

$$W - A \times 10{\cdot}75\sqrt{H} \text{ should read } W = A \times 10{\cdot}75\sqrt{H}.$$

TABLE showing current which may be safely carried by wires of various sizes.

B.W.G. No.	Diameter.	Weight per Mile.	Amperes.	Lbs. per Ampere.
	Mils.	Lbs.		Lbs.
22	28	12·4	2·33	5·32
21	32	16·2	2·84	5·70
20	35	19·5	3·27	6·00
19	42	28·0	4·3	6·5
18	49	38·1	5·4	7·0
17	58	53·3	6·9	7·7
16	65	67·1	8·3	8·1
15	72	82·5	9·6	8·6
14	83	109·5	11·9	9·1
13	95	143·0	14·56	10·0

Yours &c., CLARK, FORDE AND TAYLOR.

April 10th, 1883.

CONNECTING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your impression of March 31 (p. 473), I observe a sketch and description of a new (?) method of connecting up the main conductors with the different branches. I enclose herewith a sketch of a somewhat similar, though more perfect, arrangement for the same object, which was designed some time ago by our head elec-

Digitized by Google

trician, Mr. Walter Kirk, for an installation of 80 lights. You will see by the sketch that this arrangement is considerably more compact than the Edison Company's, and has the additional advantage of containing a safety fuse (very easily renewable in case of fusion) to each branch.—Yours, &c., W. Bridges Adams.

The following explains the diagram:—

In Fig. 1, B B is a +, and B′ B′ a — main connecting bar; C C branch connections, each fitted with a fuse; W and W′

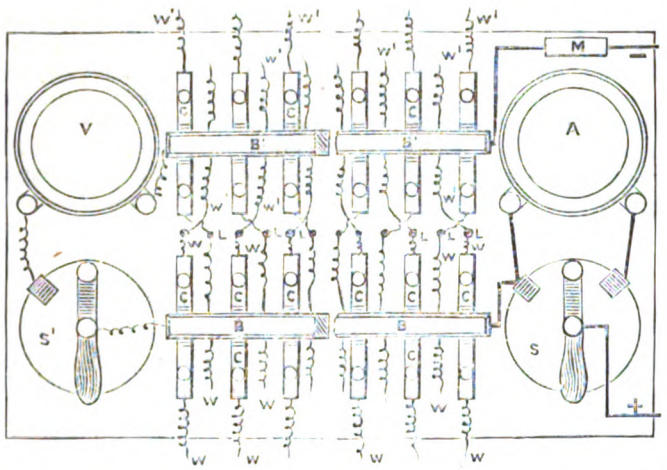

Fig. 1.—Kirk's Current Distributor. Plan View. V stands for volts, A for amperes.

are branch wires, L L lamps, S a two-way switch, either to break circuit, put in, or short circuit ammeter; S′ a switch for voltmeter.

The current enters by + wire, through S, passing either through ammeter or direct to B, then divides through branch circuits by wires, W W′, and reaching B′, finally goes by main fuse, M, to — wire.

Fig. 2 is a section through one of the bars B or B′, showing fuse, H, bent over a strip of mica, M′; S a metallic spring kept in contact with H by the head of the contact screw,

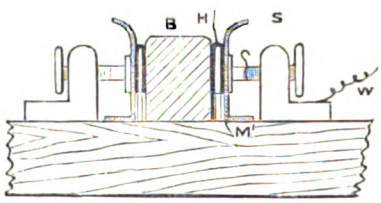

Fig. 2.—Kirk's Current Distributor. Section through one of the Bars, B or B′, showing Fuse.

which passes through branch wire terminal W. By screwing back on the terminal (thereby breaking that branch circuit), an exploded fuse may easily be replaced between B and S without fear of sparking, and then the circuit made by screwing back the screw.

EARTH CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

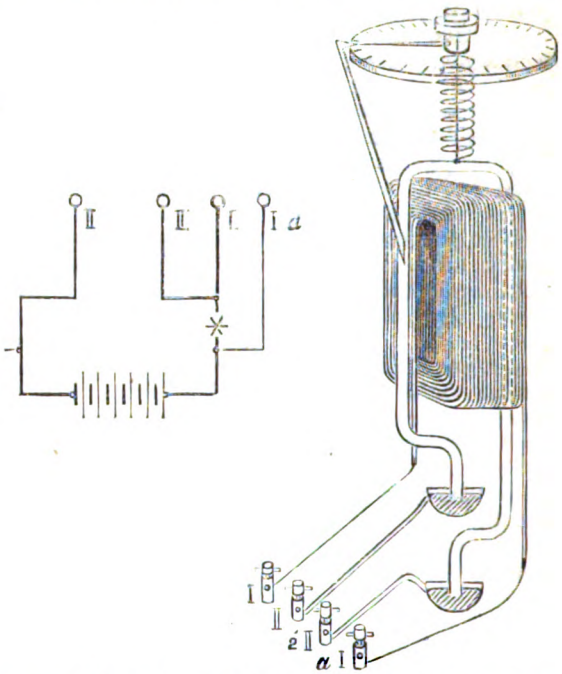
Sir: On the 15th March we had rather strong earth currents (at first mistaken for lightning) on the line between here and Teheran, and at 4 a.m. on the 16th a severe shock of earthquake occurred. Direction S.E. to N.W., lasting about one second and a half. It commenced with a subterraneous rumbling noise, and finished with two sharp jerks. I have not heard of any damage to life or property, but a dumb bell, weighing 8lb., which was lying on the floor in my bed room, was rolled several feet across the carpet and rebounded against a door with a loud report.—Yours, &c.,

J. Stanfield, C.C.

Indo-European Telegraph Company,
Tauris, Persia, March 20.

SIEMENS'S WATT METER.

It will remembered that at the late meeting of the British Association at Southampton Dr. Siemens, F.R.S., president of the association, suggested two new units, the weber and the watt, the latter being the unit for power, and in a more recent paper before the Institution of Civil Engineers Dr. Siemens described a watt meter. The accompanying diagrams will explain this instrument, which to look at is very similar to the well-known Siemens electro-dynamometer. The watt meter consists of a fixed coil of many convolutions of fine German silver wire, and, consequently, of very high resistance. The terminals are attached to the binding screws marked I and I_a in the figure. A second coil, consisting of a single convolution of thick copper wire, is hung by a thread from a torsion head, supported by the frame of the instrument. The extremities of the coil are immersed in two cups of mercury connected with the binding



Siemens' Watt Meter and Method of Connecting it up in a Circuit.

screws II and II_a. Attached to the thick wire is a pointer, showing on the scale when the coil is deflected from its zero position. A second pointer is attached to the torsion head, and reads the torsion in degrees. It is clear that if currents be passed through the two coils the thick coil will be deflected, but can be brought back to its initial position by increasing the torsion of the spring. The angle of torsion will then measure the product of the intensities of the currents. The effect of the earth's magnetism is eliminated by this null method of using the instrument. To measure the power absorbed, say in an arc light, the fine wire coil must be connected as a shunt to the arc, while the main current passes through the thick wire. The current in the fine wire will then be proportional to the difference of potential between the carbons; consequently, the deflection will measure the product of the electromotive force and current, and hence the power absorbed in the arc. A table is provided with each instrument showing the horse-power and watts, and corresponding to each five degrees of deflection of the pointer.

Telephonic Communication in Birmingham.—The National Telephone Company have arranged to provide the subscribers to the Birmingham Central Exchange with a continuous day and night service, Sundays included, without extra charge. No doubt this will be very largely appreciated, and equally, no doubt, the company will reap the benefit of their concession.

THE LIGHTING OF THE UNION SOCIETY'S BUILDINGS, OXFORD.

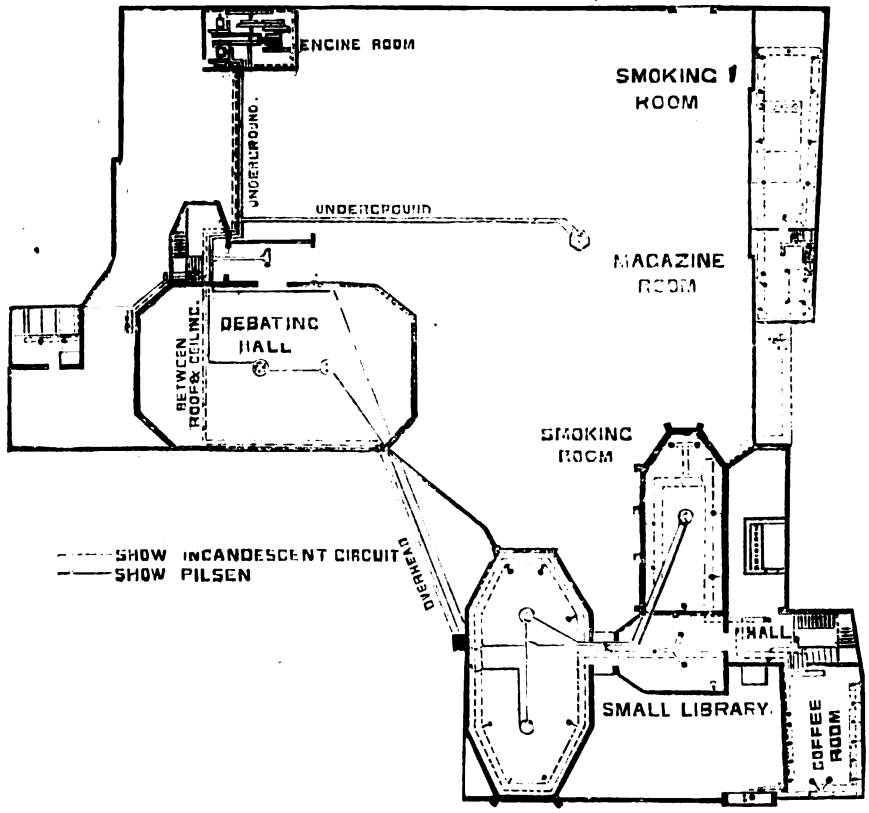
In a recent note we called attention to the fact that the Pilsen-Joel and General Electric Light Company had carried out the lighting of the above buildings by a combination of arc and incandescent lamps. Through the courtesy of the company we are now able to give an illustration of the method of running the lamps with a plan of the buildings lighted. The lamps are distributed throughout the libraries, debating hall, writing room, offices, &c. It appears that during last year's exhibition at the Crystal Palace, a committee from the Union Society specially visited the Palace with a view to adopting the electric light in their buildings, and were commissioned to report upon the best system for the purpose. The result of this visit was the selection of the Pilsen arc lamp for the large halls, as being the steadiest and least noisy of that class, and the Swan incandescent lamps for the small rooms, &c.

The following details will give some idea of the extent of this installation:—

The debating hall, whose area is 70ft. by 40ft., was previously lit with two sunlights, each consisting of 49 gas jets of eight candle-power each, giving a total light of 784 candles, at an elevation of 30ft. These have been replaced by two Pilsen lamps at the same elevation, each of 2,000 candle-power. Fifty per cent. of this light is lost, owing to the opal globes used to soften the light, so that the useful light given out is a total of 2,000 candles, or almost three times that given by the discarded gas.

The lamps are lowered for trimming and cleansing by a special arrangement of cords passing over drums fitted above the ceiling, and which are so arranged that the cable is pulled up simultaneously with the lamps, thus avoiding the disfiguring festoons usually employed. In the library, which is a handsome hall, 50ft. high by 30ft. broad and 70ft. long, are hung two Pilsen lamps to replace a large gaselier of 54 jets and 10 single lights under the gallery. The lamps are suspended about 25ft. from the floor, and their weight is counterbalanced by cast-iron counterweights, which are suspended by cords passing over drums fixed above the ceiling, and over which the cable is made to pass automatically. Under the gallery are distributed nine incandescent lamps, each of 20 candle-power, to relieve the shadows cast by the gallery; these, however, are, it is stated, not required.

The Pilsen lamps are identical with those in the debating hall, so that the total light given out is 2,180 candle-power, as compared with 64 gas jets of 10 candle-power, or 640 candles. Since the electric light has been started in this room there has been a marked difference in the condition of the books, especially those near the roof, owing to the total absence of those injurious elements which render gas so objectionable. The library walls have been decorated by old students of the university with paintings illustrating the Arthurian legends, and these are now seen to much greater advantage than previously. The next room in rotation is the writing room, which used to be lighted by four gaseliers having a total number of fifty gas jets, but by placing the electric lamps in more advantageous positions they light up the writing tables more efficiently with fourteen incandescent lamps of twenty candle-power each.



Plan of the Pilsen and General Co.'s Installation at the Oxford Union Society's Buildings. Thick lines represent the Arc Circuit, dotted lines the Incandescent Circuit.

The smoking room, which is immediately above the writing room, is furnished with one Pilsen lamp and seven incandescent lamps, to replace one gaselier of 54 jets and eight candle-power, and ten single lights, so that the light is about doubled. In the other rooms, entrance halls, staircases, &c., incandescent lamps are entirely used, and in most instances simply replace the gas jets.

The incandescent lamps are joined up in multiple series of two, so that in case of one lamp short circuiting the other in the same series serves as a safety plug, and in practice this is found to be more to be depended upon than the ordinary lead fuses which are usually employed. Fusible plugs are, however, fitted on all the main branches. The incandescent lamps are worked by a thick wire quantity machine, and the Pilsen lamps by a No. 6 Pilsen dynamo machine. The motive power is supplied by a 12 horse-power nominal Crossley gas engine, specially balanced. The power is transmitted through a 3in. countershaft, on which is keyed a 5ft. fly-wheel weigh-

Digitized by Google

ing 6cwt. Both dynamos have also balance wheels fixed to them, so that by these precautions an absolutely steady current is obtained, notwithstanding the unequal motions incidental to gas engines.

The engine room is a neat brick building, 24ft. long, 12ft. wide, and 10ft. to eaves, and is in the grounds, very near to the main buildings, and close to the adjoining street, so that it became of importance that the noise of the engine should not disturb the inhabitants. To accomplish this three exhaust boxes and one large silencing chamber, supplied by Crossley Brothers, are used, and the result has been quite satisfactory.

The accompanying sketch shows the general arrangements of the engine house and leads. The dotted lines and circles show the incandescent circuit and lamps, and the thick lines the Pilsen arc lamps. It also shows a Pilsen lamp in the garden suspended from an iron pole, which has a fine effect on the trees and grass. Formerly there was no light at all in the garden.

A summary of the installation shows:—For the electric light: Six Pilsen arc lamps of 1,000 candle-power actual, equal to 6,000 candles; 109 incandescent lamps of 20 candle-power, equal to 2,180 candles, or a total of 8,180 candle-power against 353 gas jets formerly used, giving, say 10 candle-power each, or a total of 3,530 candles. Careful readings have been taken every night of the gas consumed by the engine, and estimating as nearly as possible the number of hours that the light will be used during the year, and taking gas at 2s. 10d. per 1,000ft., the price in Oxford, it was found that the annual cost of gas (for engine) will be about £70. To this must be added about £120 for carbons and attendant's wages and other expenses; thus we get a total of £190 per annum. The gas bill paid by the society has been £250 per annum, so this leaves a margin for depreciation of electric plant.

Assuming that the cost of the electric light, with depreciation and interest, is the same as the cost of gas, the difference in favour of the electric light is very remarkable, giving nearly three times the light with all the advantages of pure air and decreased expense in redecorating, whilst the many valuable books in the society's libraries are preserved, and for fine art studies the colours can be seen as well by night as by day. This installation is in every way noteworthy as indicating what can practically be done with electric light. The work has been carried out by the Pilsen Company, under the superintendence of Mr. D. C. Smith, one of the company's assistant engineers, who may be congratulated on the successful result of his labours.

LITERATURE.

Electric Illumination. *Engineering* Series. Edited by James Dredge.

(continued from page 477.)

The chapter on "Magneto and Dynamic Generators" deals with the history and development of the modern machines from the first experiment of Faraday in 1831, and the earliest mechanical application of it by Pixii, in which, rough as it was, all the essential elements of the subject are to be found. An excellent description of the machine of Elias is given, with good illustrations, but in this description appears very plainly a disposition, which runs through the whole chapter, to dwell upon earlier anticipations and merely structural resemblances, to the disadvantage of late inventors who have taken up the subject. This machine it is said, "may be considered as a prototype of the Gramme machine," and a striking resemblance is said to exist between the one invention and the other, although the Elias was devised solely as a motor. A very slight examination of the operation of the machine will show that the resemblance is much like the proverbial resemblance between chalk and cheese. It is true that the Elias armature is a ring, as is the Gramme, but the Gramme is a true ring continuous throughout, involving a definite principle. The Elias ring is merely a mechanical arrangement of independent segments; it, in fact, is the prototype of the De Meritens ring. On the other hand, the Elias machine is the prototype of several other later machines in which the apparent resemblance is not to be seen. Its action is the same as that of Lontin and of Gramme for obtaining alternating currents, although in both of these the ring series of magnetic poles is exchanged for a radial system. In fact, the Elias machine is a regular alternating one, in which a system of electro-magnets arranged for convenience in a ring travels within a similar system, with an equal number of opposed poles maintained by a constant current.

The same disposition is shown in the remark on the invention of some unknown patentee in 1858:—"Anticipating by eight years the grand discoveries of Siemens, Wheatstone, and Varley; there is no ambiguity in the statement. The words are clear and precise. The inventor says 'it is proposed to employ the electro-magnets in obtaining induced electricity which supplies wholly or partially the electricity necessary for polarising the electro-magnets, which electricity would otherwise have to be obtained from batteries or otherwise.'" In the absence of the full specification it seems almost certain that the inventor had not the faintest conception of the principle with which he is credited; on the contrary, his idea appears to be one of the ordinary perpetual motion mistakes. The patent is for an electro-motor, "a peculiar arrangement of apparatus for obtaining motive power by the aid of electricity," and the inventor, like many others, fancied he might persuade the machine to generate the electricity for itself, seeing that it was well known that such machines would generate electricity. With much more justice it is shown that Hjorth, in 1854 and 1855, combined permanent and electro-magnets in one system in such a manner as to effect what Wilde did in 1863, when he put two Siemens machines together, and made the one with the permanent magnet supply current to maintain the more powerful one with electro-magnets, from which the working current was to be obtained. But it is no uncommon thing for later knowledge or altered conditions to enable us to see approximations to recent invention in earlier ideas, probably very imperfectly realised by the early inventor. It is unjust to the later inventor, the man who sees and points out the real thing when it is wanted, to treat him as anticipated by others who led the way to a certain point, without seeing how to go further. This applies also in the case of Pacinotti, who is credited with antedating the interesting machines of Siemens, Wheatstone, and Varley, because he included the magnet coils and armature of his machine in one circuit. But this was a mere incident of no moment. The machine was a motor, and not a generator; it was to be worked by current from an external source, for which purpose it is an insignificant detail whether the two systems are connected in series or in multiple arc; it is a pure question of resistance and arrangement of battery, and, if anything, it was the worse plan for its purpose. The principle of accumulation was not hinted at, or, indeed, available, nor did Pacinotti himself see that by changing the arrangement and purpose of his machine it would become a generator.

This in no way diminishes Pacinotti's merits, for his statements, given very fully and clearly in this work, show that he clearly appreciated and intentionally developed the principles which underlie the rotating ring armature and the commutator, which are the basis of the Gramme and other subsequent machines; especially he clearly explained the advantage of doing away with extra currents and loss of energy in magnetising and demagnetising. That he did not at all perceive the principle of accumulation is evident from the fact that in converting his machine into a generator he used permanent magnets to obtain his originating force.

The Wallace-Farmer machine is estimated rather more highly than by most people, and its going out of use attributed to the circumstance that in this country it and the Brush were "controlled by the same interests." The fact is that the machine bears no comparison with others, owing to its size, weight, and lower work power.

Digitized by Google

The various types of the De Meritens system are well described and illustrated, and a suggestion of improvement made on p. 203, which M. de Meritens will do well to carefully avoid. The Brush machine is also fully explained, but, after the custom of the writer, it is said to possess "some points of resemblance to the dynamo-electric generators of Gramme and Wallace Farmer, as well as to the magneto-electric generators of De Meritens." The fact is that it bears no resemblance whatever to any of these machines beyond the inevitable connection which exists among all the varieties of machine, which all depend upon the same natural principles. Therefore the further remark that "its principle of construction is different from that of all others, and confers upon it its special excellence and its originality," is but just.

The advantages of the Bürgin machine over the Gramme are fairly pointed out, and the machine with all its arrangements and details of construction clearly explained, so as to render its simplicity of construction and maintenance very evident, as also its working capacity, owing to the high surface velocity of the rotating armature, which its construction permits without risk of undue heating.

The Maxim and Weston machines are also fully and fairly described, and then various modifications patented by others are described, as also Edison's large machines, of which it is remarked that the armature belongs in principle to the Siemens direct current type, but the connecting up resembles the Gramme. The description of the Siemens machines of the earlier and recent types is interesting and full, and with descriptions of various later machines of more or less importance completes the chapter, which will enable the investigator to see what has been done thus far in the development of mechanical generators of current.

The chapter on Conductors gives a *resumé* of Ohm's laws and the relations of resistance, and explains clearly the different considerations involved where continuous or alternating currents are to be transmitted, and that a first-rate conductor for one may be very bad for the other, owing to the influence of capacity for charge and consequent retardation when alternating currents are used; but it is stated as the result of experiment and calculation that the effect of retardation is not of much consequence in circuits of less length than 58 kilometres. Experiments by Professor Joubert are given, showing that tarred thread gives a very inferior insulation, while the mixture of resin and paraffin gives excellent results, and the tests of Mr. W. H. Preece show the high insulation power of well-prepared ozokerit.

The different sizes of wire, or cable, employed for various purposes are given, as also a *resumé* of the modes of insulation and preparation adopted by different makers in France and England, and the information contained in this chapter will, no doubt, prove valuable to the many engineers who will have to deal with applications of electricity in the early coming time, but who have not studied the subject itself very thoroughly.

The succeeding chapter gives an account of the various processes of manufacturing carbons for the arc lamps, and a full detailed account of the preparation of the Jablockkoff candles, testing their quality, coating with copper, &c., and the amount of labour expended upon each stage of the process, which may be of interest to a limited number of readers.

The remainder of the book is occupied with full descriptions and drawings of the various forms of arc and incandescent lamps, and an appendix consisting of abstracts of patents relating to electric lighting and generators from 1837 to 1873, and a classified list of those from 1873 to 1882, and a similar list of American patents.

NUMBERS OF "THE ELECTRICIAN" OUT OF PRINT.—The following numbers of *The Electrician* are out of print, and cannot be supplied at the office, viz.:—Vol. 1, Nos. 3, 9, 19; Vol. 7, Nos. 8, 10, 12 to 18, 20, 21, 24 to 26; Vol. 8, 1, 3, 6 to 12, 15 to 26; Vol. 9, Nos. 2, 4, 24, 25; Vol. 10, No. 13. The publisher will be glad to purchase any of the above numbers.

I. THE TRANSMISSION OF POWER BY ELECTRICITY.*
II. THE PORTRUSH ELECTRICAL RAILWAY.

BY ALEXANDER SIEMENS AND EDWARD HOPKINSON, D.SC.

I. Nearly two years ago I addressed the society on the subject of "Electric Railways and the Transmission of Power by Electricity." I now venture again to bring the subject before you in conjunction with Mr. E. Hopkinson, in order to show the advance which has been made in the interval in actual applications, and to develop the theory of the subject more completely than was then possible. At the time of reading my former paper there existed only one electrical railway, viz., the Lichterfelde line, near Berlin, and even this had but a short time previously been opened for traffic. Since then Messrs. Siemens and Halske have constructed, in addition to their pioneer undertaking at Lichterfelde, a line, one and a-half mile long, from Charlottenburg to the Spandauer Bock, and a short line, worked only in the summer, in Kostverloren Park, near Amsterdam. They have also applied the system to a railway in the mines at Zankerode, in Saxony. At the International Electrical Exhibition in Paris, under the direction of Dr. Siemens, an electrical line was worked by Messrs. Siemens Frères, between the Palais de l'Industrie and the Place de la Concorde, which carried an average of over 13,000 passengers per week; and, more recently, in the north of Ireland, the towns of Portrush and Bushmills have been connected by an electrical railway, six miles long, which will presently be described in detail.

It is unnecessary to refer further to the Lichterfelde line, as the details of its construction were given in my previous paper; suffice it to say that for over two years it has worked continuously without hitch or accident of any kind.

The engine employed in the mines at Zankerode is shown in side view and in section on the diagram. The dynamo is placed with its axis lengthwise on the car, and works one pair of driving wheels by means of bevel gear. The current is conveyed along the roof of the workings by means of an inverted tee iron rail, on which a contact carriage freely slides, and connects with the engine by a flexible cable carried down the tube. The return current is taken by a similar cable and carriage to a second conductor, fixed by the side of the first. It is obvious that for mines the simpler method of using the rails themselves for conductors could not be advantageously employed, as they are in general very roughly laid, and frequently shifted, which would make it difficult to maintain proper electrical conductivity. The engine is reversible, and the handles making and breaking the current, and the brake levers, are worked from either end, so that the driver always faces in the direction in which the engine is moving. The gauge of the line is 18 in., the diameter of the wheels 13 in., the extreme dimensions of the engine—length between buffers 8 ft., width 2 ft. 7 in., and its weight 1½ ton. It can develop sufficient power to draw a load of 8 tons, at the rate of 7½ miles per hour. Without going further into details, these figures will be sufficient to show how powerful an engine it is for its bulk and weight, and its adaptability for the special purpose for which it was constructed.

Leaving for the present the subject of railways, I will now show two examples of electrical transmission of power, as illustrations of the diversity of its possible applications, and then describe the electrical lift, and use it to illustrate the general theory of the subject. First, there is here an ordinary centrifugal pump drawing water from the tank below, forcing it through the tube, and returning it again to the tank. The pump is worked by a strap from the Siemens machine, used as a motor, and the current is obtained from a somewhat larger machine, which is ordinarily used for lighting this room, but which, for the present, has been taken for the purpose of the experiment. Such a pump, coupled direct to its dynamo machine and mounted on wheels would make an excellent fire engine, as it is very easily handled, and can be started at a moment's notice by sending a current through it. At some future time, when electric mains run along our streets by the side of the water mains, there will be no difficulty in obtaining the necessary currents from "electricity" plugs placed alongside the fire hydrants. At present it would be necessary to transport secondary batteries with the electrical fire engine, but even with this drawback the great advantage would be obtained of having the full power of the pump immediately ready for use, and every minute gained is of importance. A further advantage lies in the possibility of connecting the water main direct to the pump as the pressure of the main would thus be utilised, and no water wasted. Now let the pump be disconnected, and replaced by the very small motor working the sewing machine. It is important to observe that the same generator is used in both cases, and that neither its speed nor any other of its conditions have been altered, excepting only the pull on the driving strap; but that, in the case of the pump, probably about

* Paper read before the Society of Arts on Wednesday, April 11, 1883.

Digitized by Google

5 horse-power of useful work was being done, while in the case of the sewing machine perhaps one-fiftieth of a horse-power. Now, without stopping the sewing machine, the whole of the forty Edison incandescent lamps required for lighting this room shall be connected with the generator. The sewing machine still performs its one-fiftieth of a horse-power of work, while from the same generator and the same leading wires about 5 horse-power are employed in lighting the room.

These illustrations will be sufficient to show, in the first place, that when once we have electrical mains of sufficient capacity carried from central stations to our houses, how simple a matter it will be to combine lighting with domestic operations, and even the larger operations required for purposes of trade; and, in the second place, that each motor of a series placed in parallel circuit performs the work required of it independently of all the others, and independently of the generating machine, provided only that the generator is capable of producing the power it is called upon to furnish.

This second point I will now show to you in a different form, and explain it mathematically. The diagram represents an electrical hoist, designed by Dr. John Hopkinson, and made by Messrs. Siemens Brothers. The electrical part consists of an ordinary D_3 series dynamo, fitted with reversing gear for reversing the direction of the current and the lead of the brushes, and, consequently, the direction of rotation of the machine. In the mean position both pairs of brushes are lifted from the commutator, allowing no current to pass. The dynamo runs at a high velocity, and, consequently, is connected by spur gear to the lifting axle, to diminish the speed of lift and increase the leverage. On this axle a chain pulley is fitted by means of a special friction clutch, which need not now be explained. The clutch automatically holds the weight attached to the chain as soon as the dynamo is stopped. Having coupled up the leads to the terminals of the machine, and hung a weight of one hundredweight on the chain, start the dynamo, measure roughly the speed of lift, and by means of the electro-dynamometer the current passing through the dynamo—

Weight.	Speed.	Current.
1 cwt.	4ft. per sec.	9 amperes.

Now, let the attached weight be doubled without altering any other conditions, and again measure the speed and current—

Weight.	Speed.	Current.
2 cwt.	2·5ft. per sec.	13 amperes.

You will obsereve, as you would expect, that with the heavier weight, the speed has diminished and the current increased.

Secondly, I will again put on the weight I had in the first experiment, but insert a resistance of — ohms in the leading wire. Again, measuring the current and the speed, we have—

Weight.	Speed.	Current.
1 cwt.	2ft. per sec.	9 amperes.

You will see that the current is exactly the same as before, while the speed has diminished. Taking again the double weight, and leaving the resistance inserted, we have—

Weight.	Speed.	Current.
2 cwt.	1ft. per sec.	13 amperes.

Again the same current as we had before with the double weight, but a diminished speed. From these experiments, it is clear that for a given load the current remains constant, whatever the speed may be, and that the speed principally depends upon the resistance through which the current passes.

On the diagram is shown the results of a series of experiments with the same hoist, made at the works of Messrs. Siemens Bros., under conditions which allowed of greater accuracy than is possible here to-night.

Resistance inserted in circuit, in ohms.	Work done. Load 56lb. 7·3 amperes.		Work done. Load 1 cwt. 9·2 amperes.		Work done. Load 2 cwt. 12·9 amperes.

Three conclusions are to be drawn, which are the fundamental principles of the theory of the electrical transmission of power.

I. The motor, as a machine, is entirely independent of the generator, and must be designed for the particular work it has to do without reference to the generator.

II. The current depends upon the load on the motor, and upon no other thing whatever.

III. The speed depends upon the E.M.F. of the generator, and the total resistance in the circuit of the machines. If the mains which supply the current to the motor be maintained at a constant potential, and the motor be separately excited, or have permanent magnets, the speed is proportional to the potential of the main, less the loss of potential due to the resistance of the armature.

As a practical corollary, the generator must be designed to give the current required of it by the motor, and E.M.F. sufficient after allowing for fall of potential through the resistance of the mains, to give the requisite speed. Keeping these points in view, it is easy to design a combination of machines for performing any particular work, and to calculate exactly the efficiency of the combination, and to account for the various losses that occur.

(TO BE CONTINUED.)

ON SECONDARY BATTERIES.*

BY GEORGE F. BARKER, OF PHILADELPHIA, PA.

(CONCLUDED FROM PAGE 502.)

[ABSTRACT.]

But a second form of it has been used in which the coil is made of finer wire and is placed in a shunt circuit as shown in Fig. 3. In both cases, of course, the entire current passes through the contact springs.†

After charging, the current from the secondary battery was used to maintain seventeen Edison incandescent lamps of the B pattern. More frequently, however, the battery was used in connection with the Gramme machine. The source of power being an Otto gas engine which, at best, has an explosion only every fourth stroke, the motion appears very irregular when tested by so delicate a method. As every explosion increases the speed, the higher electromotive force developed increases for an instant the brightness of the carbon filament, producing a marked pulsation in the light. If now a secondary battery of nearly the same electromotive force be placed in multiple circuit with the machine and lamps, it acts as an equaliser, and destroys entirely the pulsations. Figs. 2 and 3 show the arrangement

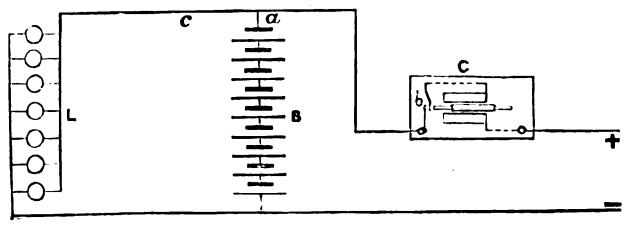

FIG. 2.

actually employed, in which B is the secondary battery, and L the lamps; the automatic cut-out being at C. When the circuit is opened at *a*, *b* and *c* being closed, the lamps are fed by the machine alone; when opened at *b*, *a* and *c* being closed, by the battery alone; when at *c*, *a* and *b* being closed, the machine

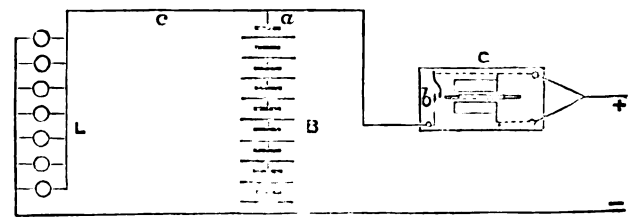

FIG. 3.

charges the battery. When all three are closed, the lamps are fed by the machine and battery together, the latter acting as an equaliser. A galvanometer inserted at *a*, *c* being opened and *b* closed, indicates the charging current; when *c* is closed and *b* open, the discharge current; and when *b* and *c* are both closed,

* From the *Proceedings* of the American Association for the Advancement of Science, Vol. XXXI., Montreal Meeting, August, 1882.

† Sir Wm. Thomson has devised a polarised cut-out for this same purpose. He exhibited it at the York meeting of the British Association in September last.

the equalising current. If the electromotive force of the machine-current be but slightly in excess of the battery current, the deflection to the right in the first case will about equal that to the left in the second; so that in the third case the deflection is practically zero, not the least spark appearing on opening at *a*; and this, though the pulsations are completely destroyed, the light being perfectly steady. The advantage of a much more agreeable light is thus secured; but in addition the life of the lamps must be increased by the use of this steadier current, as it has been shown to be by using the secondary battery alone.

On the 27th of February the battery was charged continuously for fourteen hours, or until hydrogen was freely evolved from each of the thirty-two cells employed. It then gave an electromotive force of 59·3 Daniell cells; or calling the Daniell 1·08 volt, of 64·04 volts. On the 10th of June, the same thirty-two cells gave an electromotive force of 56·7 Daniell's, or 61·2 volts. On the 24th of June, their electromotive force was 54·3 Daniell's, or 58·6 volts. It may be assumed, then, that the average electromotive force of a single cell was not far from two volts. This value has never been exceeded in any of the measurements made, either on single cells or on groups of cells. When first made, the resistance of the single cells was low, about 0·02 ohm; but subsequently the internal resistance increased considerably, rising even to twice this value.

The chief defect of the secondary lead battery is the local action which takes place in it. By local action is meant any deterioration in the efficiency of a battery which occurs when it is left on open circuit. This defect was noticed by Planté, who says:—"If the lead peroxide deposited on the positive plate had no tendency to spontaneous reduction in the acidulated water, by forming a local circuit with the metal that it covers, the preservation of the charge taken by the secondary couple should be indefinite. But this peroxide is reduced, and with the more facility as the layer of it is thinner. In a new secondary couple the charge cannot be preserved." In a well formed battery he attributes the preservation of the charge to a reduction of the superficial layer to monoxide, which acts as a protecting coating. Another local action, however, takes place in this battery, which appears to be of more importance. This is the action of the sulphuric acid upon the products of electrolysis. The finely divided lead on the negative plate, as well as the peroxide upon the positive, is alike converted into sulphate by this action. When the circuit is closed this action is normal; but it takes place equally well when the circuit is open. It is then abnormal, and, of course, injurious. The formation of lead sulphate in the secondary battery has been studied by Gladstone and Tribe.* They found that with a Planté cell the whole of the peroxide formed on charging was converted into white sulphate within seventeen hours. The same fact was observed with the Faure battery. So far, however, from regarding this formation of sulphate as wholly injurious, they regard it as "absolutely requisite in order that the charge should be retained for a sufficient time to be practically available." They believe that the insoluble lead sulphate clogs up the interstices of the peroxide and after a while forms an almost impermeable (*sic*) coating between it and the lead plate; so that the mass of peroxide which is in contact with the lead plate expends its energy slowly, while the same mass of peroxide, brought into connection through its own lead plate with another lead plate at a distance, expends its energy even through the sulphuric acid, in a tenth or a hundredth part of the time.

My experiments with the Faure battery above described confirm entirely those of Gladstone and Tribe as to the formation of lead sulphate. In several cases, the acid in charged cells disappeared entirely on standing so that the water was tasteless; and in some instances this was repeated three times with the same set of plates. This action increased very greatly the internal resistance, first by replacing the acid by water and second by forming the higher resistant sulphate. On examining the plates, lead sulphate formed the entire coating upon both of them. On attempting now to recharge such a cell, this notable increase in the resistance showed itself in the reduced current transmitted by the same electromotive force. Gradually, however, the resistance fell and the current finally regained its normal strength. In one instance the charging current rose from two amperes to 12, in four hours, 28 cells being in circuit, arranged in series. It was observed, however, that when the current was first applied torrents of gas were evolved from both plates; and that as the charging process went on the oxygen was first completely absorbed and then the hydrogen. When the charge was nearly complete the evolution of hydrogen reappeared. There would seem, therefore, to be a very considerable loss of energy, due to the resistance consequent upon the formation of sulphate. In the first place the current energy is wasted as heat in the cells; and in the second, a large portion of it is dissipated in the evolved gases.

Another defect of considerable magnitude is developed when a number of secondary cells is placed in series, and is due to a want of uniformity in their capacity for storage. This arises, probably, first, from the difficulty of constructing them exactly alike originally, and, second, from the impossibility of uniform action among them on charge and discharge. The difference in the cells of the same battery even, when they all have been treated precisely alike, is surprising. On the 14th of June, 32 cells were freshly charged, and the current strength from each cell measured on a tangent galvanometer. Eleven cells gave 80deg. deflection each, 17 gave 79deg. each, one gave 78deg., one 77deg., one 75deg. and one 20deg. When 17 Edison B lamps were placed in circuit, the discharge deflection of the 32 cells in series was 67deg. On the following day the battery was charged again, and, after an hour's use on the lamp circuit, was again tested. Those giving a deflection of 87deg. were two; of 86deg., two; of 84deg., two; of 83deg., one; of 81deg., one; of 78deg., five; of 77deg., two; of 76deg., one; of 13deg., three; of 11deg., one; of 10deg., three; of 8deg., one; of 6deg., one; of 5deg., three; of 4deg., one; of 2deg., one; of 1deg., one; and of 0deg., one. Obviously, so long as any peroxide is present, the electromotive force is constant; hence this wide variation of current strength must be attributed, apparently, to the variation of the resistance in the different cells. But this is not the worst aspect of the matter. If the discharge be continued for a longer time, some of the cells become exhausted sooner than others, and are then charged in the inverse direction by the current from the rest. On the 12th of June, the thirty-two cells, after pretty complete discharge, were measured as above. Nineteen cells gave positive deflections ranging from 87 deg. to 5 deg.; thirteen gave negative deflections varying from 13 deg. to 1 deg. Faraday said of primary batteries in 1834, that "weak and exhausted charges should never be used at the same time with strong and fresh ones in the different cells;" and this remark is even more applicable to secondary batteries, where this condition is more liable to occur. Not only does a dead cell introduce resistance into the circuit, but what is of more importance, its reverse polarisation introduces a counter electromotive force, so that every such cell neutralises another cell, the dead resistance of which is also added to the circuit. In consequence, it is not safe in practice to draw from a secondary battery all the energy it should be capable of yielding, and in most cases not more than half can be safely taken out of it. In place of continuing uniform as in a single cell, the electromotive force of a series of cells begins to fall when about half the charge which it ought to be capable of yielding has been drawn from it. The practical result is that to supply for lighting a definite number of coulombs of electricity, a secondary battery of twice the size is necessary under these circumstances.

With reference to the two forms of lead secondary battery devised by Planté and by Faure respectively, my experiments show that while the electromotive force is the same in both, and while the internal resistance and storage capacity may readily be made the same, yet that the local action is far less when the peroxide is formed by the action of the current upon the lead plate itself than when it is produced from minium spread upon it. The rapidity of the formation of the peroxide is proportional to the density of the current; but when rapidly formed it is fine and spongy. In one of my Planté cells, the peroxide is beautifully crystalline and very hard. Not a trace of sulphate has been formed in it apparently, though it has been in use for six months, and has been frequently charged and discharged during that time. The necessarily finer condition of the peroxide in the Faure battery would seem to predispose it to a more considerable local action. True, the Faure battery requires very much less time than the Planté to form it. But this is more than compensated by the increased permanence of the latter. With an equal storage capacity, as in M. de Kabath's form of Planté cell, it would appear that in efficiency it will surpass the form devised by Faure.

The commercial aspect of the question of the storage of electrical energy has recently assumed a very considerable importance. But it is evident at the outset that an agent, which has been produced and then stored, must cost more when redelivered than when first produced, by exactly the cost of the storage; that is, supposing there is no loss in storing. But there is a loss, and this is almost, if not quite, one-half of the energy involved; as it would seem from the Conservatoire experiments in Paris, among others. The first cost of the accumulators, the expense of charging them, their low efficiency, and especially their bulk and weight, must ever prevent, it would seem, their competing successfully with the direct use of the dynamo-electric machine, at least with any form of secondary battery yet devised. For special uses, however, the storage battery has a high value. Even

* *Nature*, XXV., 221, 461; XXVI., 251, 1882.

Digitized by Google

if the cost of an ampere of current produced by it is twice as great as if produced directly by the dynamo machine, this cost is only one-half of that required to give the same current by any available form of primary battery. Where a strong current of low electromotive force is needed, under conditions where a dynamo cannot be employed, there the secondary battery has its most important field. Its value rapidly decreases as the number of cells is multiplied, as when a high electromotive force is needed for the production of light. Its chief advantage is its transportability; since by placing it near the work to be done the loss of energy on long conductors is obviated.

MAGNETISM.

BY JOHN T. SPRAGUE.

1. The magnetic property of a natural substance, ferrosoferric oxide F_3O_4 or $FeO + Fe_2O_3$, known as the loadstone, was discovered in early times from its power of attracting and adhering to iron. It was afterwards discovered that the loadstone imparted its powers to steel, and that masses of steel thus acquired a variety of peculiar properties besides that of merely attracting iron.

The first striking property is a directive power by which a bar of magnetised steel always places itself in one position, with one end pointing towards the north; the next is that when two such bars approach each other two of the ends attract and two repel each other, instead of displaying a constant attraction, as with iron.

2. In examining these properties we find that the force, be it what it may, which is acting, is concentrated mainly at the two ends of the bar, towards which the holding power on iron is greatest; thus, if a bar magnet be rolled in a mass of iron filings, these will adhere to it in the manner shown in Fig. 1;

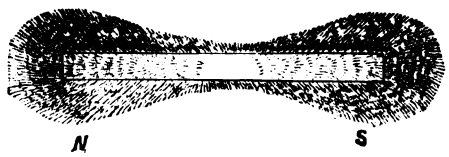

FIG. 1.

so if it is measured by the actions on a suspended needle, the force is represented mathematically by a curve shown in Fig. 2, which exhibits half a bar magnet, and shows that the point of greatest force, or what is called the pole, is not at the actual extremity, but a distance within, varying with the length and form of the magnet. These figures are identical with those

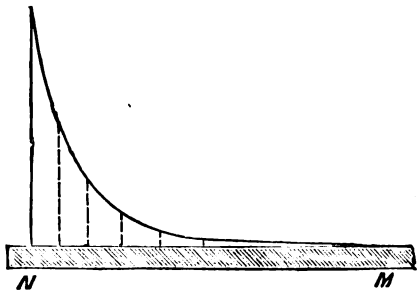

FIG. 2.

which represent the distribution of electricity, and hence there was early perceived a relation between magnetism and electricity, and this naturally, in times when men never hesitated to create any power which would serve to explain a fact, led to the hypothesis of two magnetic fluids, the Austral and Boreal, now entirely abandoned, although their brethren, the electric fluids, are still cherished by many philosophers.

3. A remarkable feature in magnetic force is that it apparently acts at a distance without relation to intervening substances, providing these are not themselves magnetic. Different substances, such as iron, nickel, and, to some slight extent, all bodies, have *magnetic capacity* in varying degree, but this is unlike electrical capacity. In electricity all materials have equal capacity as to the surface charge, but different capacities as to forming the field of force. In magnetism the different capacity is in receiving and retaining the charge of force, while the surrounding field forms equally in all bodies not themselves magnetic. Hence a magnet acts just as powerfully through a sheet of glass as through air. If, therefore, we place a sheet of glass over a bar magnet, and sift iron filings over it, these arrange themselves in obedience to the force, if we lightly tap the glass to aid them in moving. Fig. 3 shows the result, the filings arranging themselves in closed curves which exhibit the lines of force surrounding the magnet, and on which, or, rather, on the tangent to which, at any part, a suspended magnetic needle will place itself. This figure represents, therefore, a section of a magnetic field; the field itself of course extending round the magnet in all directions. It also enables us to perceive that magnets do not act simply at a distance; they induce in all surrounding matter a condition which is the source of magnetic action; but it is only some forms of matter, of which iron is the most important, which render this condition active as magnetic force, and are themselves capable of retaining that condition, and transmitting it afresh.

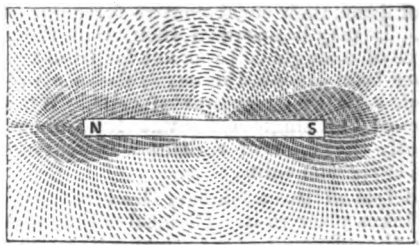

FIG. 3.

The forms or curves which may be obtained in this manner vary infinitely according to the position of the several poles in a field; they are in fact formed upon precisely the same principles as are explained in my article on the induction and conduction circuits, p. 247, and render visible in magnetism the lines and fields of force which can only be perceived by the imagination in electricity.

4. To understand the magnetic condition, we must examine the magnet itself. Thus far we see in it a resemblance to electrified cylinders with the + and − charges apparently collected upon their separate ends. If, however, one of those cylinders is divided across the middle, we obtain the two parts in the opposite states, one wholly +, the other wholly −, and there is thus some ground for the idea that we have really separated two fluids. But this is not the case if we break a magnet across, for we find that two perfect magnets are produced, two fresh and opposite poles being generated out of the previously inert middle, while the forces these possess are taken from the original terminal poles, the attractive powers of which

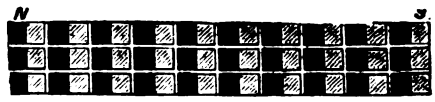

FIG. 4.

are reduced. We may repeat this process to an unlimited extent till we convince ourselves that the perfect magnetic power resides in every minute particle; in fact, that magnetism is a force belonging to and residing in the molecules of which the magnet is composed. This view of the nature of a magnet is well expressed by Fig. 4. This presents the magnet as consisting of a collection of polarised molecules symmetrically arranged, the force of each series exhibited at its two ends, and completing the circuit of polarisation or force through surrounding matter in the curves shown in Fig. 3. This conception is strictly correct as to the facts of magnetism itself; but when we come to the theory and to the evident connection of magnetism and electricity, it is apt to generate confusion of ideas, owing to the apparent resemblance between the polarised molecules in both cases.

5. To avoid this confusion, and more intelligently to examine the facts and the true relation of the two forces to each other, and to the molecules of matter, it is desirable to define those relations in accordance with the relations of electricity to mater. Electricity and magnetism then are the same force, and are two actions of polarised molecules, manifested at right angles to each other, and both developed together. Electricity is the action which occurs *in the line of polarisation*. Magnetism is the action which occurs *at right angles to the line of polarisation*, and in all directions at right angles to that line. But there are some important distinctions to be noticed. Electricity is essentially a dynamic force; its nature consists in producing motion in, and transmitting energy along, the polarised chains; its static actions are only incidents of this process dependent on the resistance offered to the completed motion. Magnetism is, on

Digitized by Google

the other hand, purely static; it consists in the storing up of energy in the polarised molecules. It should also be remarked that while magnetism is an essential consequence of and attendant upon electric polarisation, it is only manifested as magnetic action by certain substances which possess the faculty of assuming that condition which constitutes a magnet; of these iron, nickel, and cobalt are the most effective, and this state is only produced and manifested by dynamic electricity, and in degree proportioned to its quantity. Considered from this point of view, Fig. 5 represents a typical molecule, and this figure thoroughly mastered and fixed in the memory will answer every possible question as to the relations of magnets and currents, the action of helices, galvanometers, coils, &c. A magnet

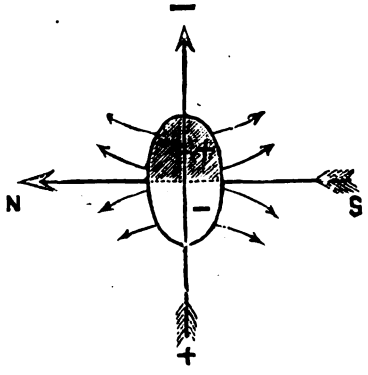

Fig. 5.

will always place itself at right angles to such a molecule (forming, of course, part of a polarised chain), with its north end to the left hand, looking from the molecule itself, so that the arrow or magnet N S is supposed to be on the farther side of the molecule. There is, however, no true directive force in this action, no north and south *sides* to the molecule itself, as there are + and — *ends*, but the directive tendency is the same at right angles to *any radius* of the molecule at right angles to its line of polarisation. Thus, if the molecule or current be vertical, and a suspended needle be carried round it, the needle will retain the same relative direction to the molecule, but will make an entire revolution on its own axis, and its extremities will point in turn to every direction, provided the directive action of the earth is neutralised, as by a fixed reversed magnet.

Fig. 6 will illustrate this. A shows a section of a conductor carrying current, or of the molecule in Fig. 5, with its radial lines at right angles to which external magnets will place themselves. B represents a filament of a magnet such as is shown in Fig. 4, which conveys a correct idea of the *magnetic* polarities

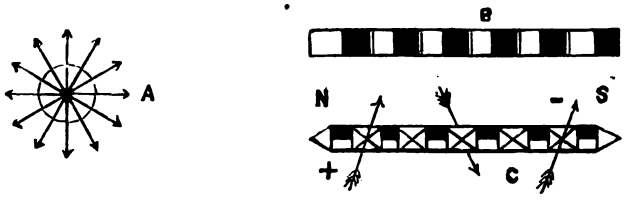

Fig. 6.

in successive sections, while C exhibits the circular polarisation in these sections, which is the probable electrical cause of the magnetic force. The arrows show the directions of a current which would set up this polarisation, and generate the N S magnetism shown.

By aid of these figures the student may realise the idea usually employed since Ampère devised it in order to fix on the memory the relations of magnets and currents; for, let the reader conceive himself *to be the molecule*, Fig. 5, the current of which he forms part, entering at his feet, his head, therefore, being the + extremity; his right hand will have the magnetic actions of a N pole to any object at which he is looking, and therefore any magnet in front of him will present its N end to his left-hand, the magnet itself standing fairly across him in front in whatever direction he may turn.

7. *Ampère's Theory.*—As before remarked, magnetism was formerly explained by the invention of two fluids; but the theory now generally received is that of Ampère. Working from the fact that a circular electrical current constitutes a magnet at right angles to its plane, and that electro-magnets are practically composed of a series of such circular currents ranged in the form of helices, and also from the fact that the force is evidently possessed completely by the molecules of permanent magnets, he taught that magnetic substances are composed of molecules around which electric currents are always flowing; that in the unmagnetised condition these molecules and currents are arranged haphazard in all directions, and that the act of magnetising consists in arranging them in parallel order. Fig. 7 exhibits this theory; it shows the magnet built up of the molecules with their currents acting as does an external current shown by the arrows. The bar S shows a longitudinal view of the same magnetic system. The theory explains all the facts of magnetism, but beautifully scientific as it is, there are fatal objections to it, not generally seen. In the first place, it is based

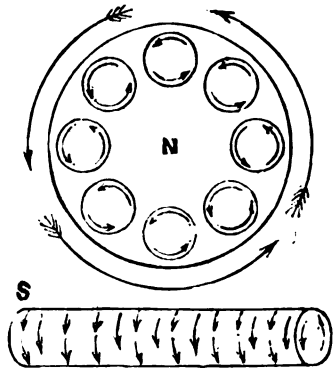

Fig. 7.

on the idea of electricity being an entity, a something which can circulate round the molecules in a real stream, and therefore it is inconsistent with more recent views as to the nature of electricity; but apart from this, though we might assume it to be possible that such circulating currents might be confined to the molecules, it is impossible to conceive how they fail to arrange themselves symmetrically always, or why, once arranged, as in magnetised iron, they derange themselves at once the moment the inducing magnet is withdrawn. The very nature of electric currents would require a *coercive force* to prevent the magnetic condition being always existent, whereas the reverse is the fact.

8. *The Molecular Theory.*—This theory of electricity is equally adapted to magnetism, takes possession of all Ampère's work, and adopts all the facts and all these are unaffected by the substitution for the assumed circulating molecular currents, of the conception of the polarised molecule exerting influence upon all the neighbouring molecules and arranging them in systematic polar order. Fig. 8 shows at a glance both the remblances and differences of the two theories. N shows the molecules retained as a polarised chain, analogous to the conditions of static electri-

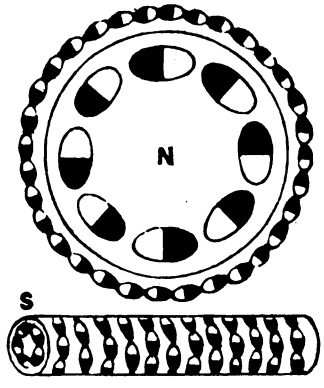

Fig. 8.

city, and it shows how an electric current generates this state in a bar around which it circulates. The coercive force of the magnet is due to the resistance of the molecules to the change of condition, either to being magnetised or demagnetised in the case of steel, the molecules of which are compound, while iron has little power to resist either. What gives the molecules of iron and steel these properties we do not know. But certain properties are apparently connected with the atomic weights of the elements, which have been classed into groups dependent on numerical relations of these weights. A Russian savant, M. Mendelejeff, has found some difference of properties according to whether the atomic numbers belong to an even or an odd series, as to which information may be found in the second supplement to Watts's

Digitized by Google

"Dictionary of Chemistry." It appears that magnetic bodies all belong to the even series, and that diamagnetic bodies belong to the odd series, and that as to these latter the diamagnetism increases with the atomic weight.

9. Those who desire to study magnetism thoroughly will find some useful suggestions as to experimental means in papers by Dr. Shettle to be found in Vol. III., pp. 10 and 44 of *The Electrician*. His object was to show that magnetism is a spiral force rather than a longitudinal one, but his theory involves, like Ampère's, a continually maintained current of energy, and it is difficult to conceive how such a current can be maintained. The spiral order of the molecular arrangement both as to magnetism and electricity may be almost considered to be established by the experiments of Professor D. E. Hughes, who gave to the world the microphone and the induction balance; he has proved that the passage of a current through an iron wire produces in it a permanent molecular strain, which is evidently of the nature of a twist or spire, the direction of which depends on that of the current; this twist can actually be removed by a mechanical twist in the opposite direction, or by the application of a magnet pole. He also proved that this molecular twist, in the act of being untwisted mechanically, generates an electric current, just as does the ordinary cessation of magnetism. Professor Hughes has recently extended these observations in examining the nature of steel as an alloy of carbon and iron, and into the effect of "temper." His results promise important practical teachings and useful modes of testing the quality of steel as suited to different uses, and his papers should be studied by those interested in these subjects. The apparatus for the investigation is very simple; it consists of a tube with a coil of wire upon it, through which the wire to be examined passes and becomes the core of an electro-magnet; a battery and an interrupter is connected either to the coil or the wire, and a telephone to the other; each mode of connection has its use according as it is desired to observe the molecular effects produced on the core by a current, or the reactions of the wire in generating currents in the coil (when the battery would not be used) under the influence of torsion.

10. A magnet is usually thought of as merely a piece of steel in which a certain force resides; it is evident that this is only a part of the magnet; the external field of force which accompanies it is as essentially a part of it as the steel itself, and the actions of magnetism are all of them merely transfers of the energy of this field and rearrangement of its lines of force. The directive energy of the magnet is due to the inductive action of the energised molecules, tending to range all neighbouring molecules in the same order as themselves. They thus set up a magnetic field (which is a resolution of the forces exerted by the various acting molecules) in which all the particles of air and common matter range themselves, like the filings in Fig. 3; when a magnetic body enters this field its molecules range themselves in obedience to it, and by their own power set up a field of their own; when the body entering the field is already magnetised permanently, and therefore has its molecules already so ranged, or is temporarily magnetised circularly by being the conductor of an electric current, then, if movable as a mass, it is turned or attracted, or apparently repelled, in such manner as to most energetically form part of the original lines of force or magnetic field; but if it cannot move it reacts upon the field and moves the magnet if movable, and a new field is set up which is the resolution of the forces of the two or more magnets within it.

SLIP

HONOURS FOR AN ELECTRICIAN.—Her Majesty has been pleased to confer the honour of knighthood upon Dr. C. W. Siemens, F.R.S.

INDO EUROPEAN TELEGRAPH COMPANY.—The next ordinary general meeting of this company will be held at the Cannon-street Hotel, on the 30th inst., at twelve noon.

CHANGE OF ADDRESS.—The River Plate Telephone and Electric Light Company have removed their offices to 34, Walbrook, E.C., and Mr. R. H. Krause has been appointed secretary.

ELECTRIC LIGHTING IN THE CITY.—The Commissioners of Sewers have agreed to continue their contract with the Maxim-Weston Company for a further period of three months, at £400.

A VOLUNTEER TELEGRAPH CORPS FOR INDIA.—It has been suggested that a special telegraph corps should be formed of the volunteers in India who belong to the Telegraph Department.

MONTEVIDEAN AND BRAZILIAN TELEGRAPH COMPANY.—This company give notice that they will pay the dividend of 2s. per share, declared at their meeting on the 5th inst., on and after the 30th inst.

OPPOSITION TO THE ELECTRIC LIGHT.—The Westminster District Board of Works is organising a meeting of delegates from those local authorities who are opposed to the introduction of the electric light.

THE CHARING CROSS ELECTRIC RAILWAY.—The consideration of the Charing-cross Waterloo Electric Railway Bill by a select committee of the House of Commons has been postponed to Tuesday, May 1.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended the 15th April are £4,026, as compared with £3,754 in the corresponding period of 1882.

ELECTRIC LIGHT LEADS.—With our next week's issue we shall publish No. 3 of our Supplements, which will be in the form of a table giving the loss of potential in volts, in 100 yards of outgoing and returning lead.

THE WEST COAST OF AMERICA TELEGRAPH COMPANY.—This company give notice that the tariff from Great Britain to Buenos-Ayres, and all stations in the Argentine Republic, viâ Galveston, has been reduced to 13s. per word.

FRANCE AND THE VIENNA EXHIBITION.—A decree has been published authorising an extraordinary grant of 80,000 francs to the French Ministry of Posts and Telegraphs for expenses in connection with the Vienna Electrical Exhibition.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 13th April, 1883, were £2,474, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

COPPER WIRE.—We have received a copy of a useful table just published by Messrs. Walter T. Glover and Co., of Manchester, giving the relations between the dimensions, lengths, resistances, and weights of pure copper wire, from 0000 B.W.G. up to 30.

AN ACQUISITION.—We learn that Mr. Frost, Librarian to the Society of Telegraph Engineers and of Electricians, has secured for the library of that society the large collection of pamphlets relating to Electricity and the Electric Telegraph collected by the late C. V. Walker, F.R.S.

THE ARREST OF M. PHILIPPART.—A *Times* telegram, dated Brussels, April 12, stated that M. Philippart, the Belgian financier who was arrested in Paris, would probably be given up to the Belgian authorities, as his books were discovered to have been tampered with.

PHŒNIX ELECTRIC LIGHT COMPANY.—The liquidator of this company, Mr. Henry Bishop, has given notice that all creditors of the company must send particulars of their claims to him at 41, Coleman-street, E.C., before the 10th May. The date for adjudicating upon the claims has been fixed for the 23rd May, at 12 noon.

ELECTRIC LIGHT IN EDINBURGH.—On Tuesday night, between eight and nine o'clock, the Brush Electric Light Company of Scotland had one of their arc lights, with a large reflector, in operation at an opening in the wall of their premises in Market-street. The apparatus was on a swivel, and was turned rapidly here and there to show its power of illuminating distant objects.

THE FRENCH MINISTER OF TELEGRAPHS.—M. Cochery, French Minister of Posts and Telegraphs, accompanied by M. Hérisson, the Minister of Commerce, and M. Felix Faure, Deputy for Havre, arrived in Liverpool on Monday afternoon on a visit of inquiry in reference to the English mail system. A further object of their visit is to obtain information as to the working of the English Postal and Telegraph Services.

THE EDISON SYSTEM IN NEW YORK.—The Western Union Telegraph Building, at the corner of Broadway and Dey-street, New York, is about to be lighted from the Edison Central Station. An American contemporary says that it is being wired for 345 lamps, though at present but 255 are to be used. These are distributed as follows:—Associated press room, 55; operating room, 107; ground floor, 55; halls, 8; first and second floor, of No. 8, Dey-street, 15 each.

THE TELEPHONE IN BUENOS AYRES.—The *Buenos Ayres Herald* of 20th March last informs its readers that the Pantelephone Company of that city has agreed to unite with the Bell Telephone Company, under the joint title of "La Union Telefonica del Rio de la Plata." The chairman of the company is Major Alexander Wood, of the Western Brazilian Telegraph Company, and its managing director Mr. F. W. Jones, late general superintendent of the Telephone Company of Brazil.

SOCIETY OF TELEGRAPH ENGINEERS.—At the meeting of the society to be held at 25, Great George-street, S.W., on Thursday, April 26, at 8 p.m., the discussion will be continued on the following papers:—"On Some New Forms of Telephone Transmitters, with a Note on the Action of the Microphone," by John Munro, Associate; "On the Influence of Surface Condensed Gas upon the Action of the Microphone," by I. Probert and Alfred W. Soward, Associates; "On Microphonic Contacts," by Shelford Bidwell, M.A., LL.B., Associate.

ELECTRIC AND OTHER CLOCKS IN GLASGOW.—At a recent meeting of the Glasgow Town Council it was stated that the Bazaar Committee "had twice visited the 18 electric clocks in the city, and on each occasion had found them all correct. The 19 turret clocks under the charge of the committee had also been visited, and 10 were found correct, 8 being slightly wrong and 1 standing." It is hardly necessary to add that the council were so favourably impressed by this report that it was proposed to take steps to have the 19 turret clocks regulated by electricity. In the end, however, the matter was referred back to the committee for consideration.

A NON-INFLAMMABLE INSULATING MATERIAL.—Mr. W. A. Phillips, of Homerton, and Mr. S. E. Phillips, of Charlton,

Digitized by Google

have taken out a patent for an improved method of making the insulating bodies of electric light conducting wires non-inflammable. The invention consists in passing the wires, covered or uncovered, through a solution of tungstate of soda. According to another part of the invention a concentrated aqueous solution of tungstate of soda is prepared and poured into boiled linseed oil, which is heated and kept stirred until the water has evaporated. A portion of this fluid is then mixed with the insulating compound used to cover the wire. The number of the patent is 2571, and it is dated 31st May, 1882.

Sixpenny Telegrams.—In *The Times* of the 18th April there were three letters on this subject, one from Mr. Horace Lennard, stating that the plan suggested by Mr. Latimer Clark in a previous issue of having fast and slow telegrams was already in vogue in the United States, and had proved itself to be practicable. The second letter was from Mr. H. Weaver, managing director of the Anglo-American Telegraph Company, who proposed the adoption for inland telegrams of the "word" system of charging messages. One halfpenny to be charged for each word, free addresses to be done away with, and senders to be allowed to forward any number of words they like. The third letter was an appeal from Colonel F. T. Maitland for the extension of the telegraph to country districts.

The Porterage of Telegrams.—In the House of Commons on Thursday week, Mr. Dalrymple asked whether it would be possible to reduce the present charge of 1s. per mile for the delivery of telegrams in the country, to which Mr. Fawcett replied that the charge of 1s. per mile was for the delivery of telegrams by mounted messengers at distances of three or more miles. The whole charge was paid over to the messenger, and the Post Office made no profit out of it. In Ireland, where mounted messengers could generally be procured at 8d. a mile, that was all that was charged. It was only the actual cost of delivery that the public were required to pay in any case, and if a message could be sent by a foot messenger instead of a mounted messenger at a cheaper rate, no objection was made to this being done.

Electric Lighting at Kimberley, South Africa.—We have received the following description of the installation, on the Brush system, which has been working for some time past at Kimberley, in South Africa, from a correspondent. He writes:—"The installation consists of 32 Brush arc lamps, supplied by two 16-light machines driven from a countershaft by a Robey engine of 20 nominal horse-power, which makes 130 revolutions per minute, the machines going at 800 per minute. One circuit, three and a half miles in length, extends round the Kimberley mine, the other circuit, four miles in length, to De Beer's mine, down Du Toit's Pan and Victoria Roads. The wires are carried partly on the roofs of the houses, partly on iron poles. The light is at present giving great satisfaction. The work has been carried out under the superintendence of Mr. R. L. Cousens, A.S.T.E. and E., electrician to the South African Brush Electric Light and Power Company."

Electrical Exhibition at Philadelphia.—A circular issued by the Treasury Department of the United States in regard to the electrical exhibition to be held by the Franklin Institute, at Philadelphia, states that "articles arriving at the ports of Boston, New York, or Baltimore, destined for the exhibition of 1883 or 1884, may be shipped by bonded common carriers from the port of first arrival to Philadelphia. On arrival at Philadelphia they will be taken possession of by the collector of customs, and an entry for warehouse in the usual manner will be required, after the bonding of the exhibition building, whereupon an appraisement will be made, and the rate and amount of the duties determined. Storage of the merchandise will be permitted in a portion of the building, duly bonded. Goods withdrawn for consumption on payment of duties, after one year from the date of their importation, will be subject to an additional duty of 10 per centum of the duties otherwise accruing."

Electric Fire Alarms.—We understand that Messrs. Griffith and Co., Telegraph Engineers, of 4, Queen Anne's-gate, S.W., have, with the sanction of the Metropolitan Board of Works, on the recommendation of Captain Eyre Shaw, C.B., Chief Officer of the Fire Brigade, arranged to provide, tentatively, six fire alarms in connection with the King-street Fire Station in that portion of the Western District which comprehends Golden-square, Piccadilly, Pall Mall, St. James's-square, Bruton-street, and Oxford-street (near the Pantheon). The apparatus supplied by Messrs. Griffith and Co. is known as "Spagnoletti's System," which was exhibited at the International Electric Exhibition of Paris, 1881, and will, in the course of a few days, be placed in the streets above-named, under the direction of the Engineer in Chief of Her Majesty's Telegraphs. Mr. Spagnoletti's apparatus was illustrated and described in our issue for August 12, 1882, p. 296, of Vol. IX.

Great Northern Telegraph Company.—According to the accounts of this company for the year 1882 the traffic receipts have brought in £239,864; interest, £8,181, and sundries, £8,810, which, added to a balance on the 31st December, 1881, of £19,689, brings up the total receipts to £276,544. The expenses during the year were distributed as follows:—Salaries and wages, £35,678; expenses of stations, offices, and agencies, £10,182; supervision and maintenance of sea and land lines, and repairing steamers, "H. C. Œrsted" and "Store Nordiske," £9,637; instruments and cells, £1,966; maintenance of buildings, £529; travelling expenses, £651; which, with sundry other minor expenses, made up a total of £71,214. The company paid 5 per cent. on 150,000 shares, = £75,000, and 3 per cent. as an extra dividend on the same number of shares, = £45,833, or a total of £120,833. They added £55,555 to the reserve fund, and £1,111 to the pension fund; paid, £1,500 in directors' fees, and carried forward a balance of £16,579.

Improvements in Secondary Batteries.—According to Patent No. 2602 (June 2, 1882), taken out by Sir C. T. Bright, the inventor divides each cell of his battery into two parts by a porous diaphragm, each part being filled with a number of leaden granules and dilute sulphuric acid. Leaden plates are placed in each part of the cell. Another part of the invention consists in covering the surface of plates with dioxide of lead by first exposing them to the warm vapours of acetic acid and carbonic acid gas, thus converting the outer surface into carbonate of lead, and afterwards treating it with chlorine gas. Another improvement consists in mixing dioxide of lead in the form of powder with the leaden granules above described. According to another patent, No. 2658, dated the 6th June, 1882, the inventor, Mr. A. Muirhead, of Westminster, claims the preparation and formation of the metallic electrodes of secondary batteries by placing the plates in a vat, through which a stream of a solution containing lead is caused to flow, and then producing deposits upon the plates from the said solution by the electrolysis of the liquid.

Electric Lighting at Dewsbury.—A very successful exhibition of the electric light has just been brought to a close in connection with the new Dewsbury and District

Digitized by Google

Infirmary. During the exhibition, which lasted over four weeks, the building was brilliantly lighted by arc and incandescent lights, which were supplied by the Yorkshire Brush Electric Light and Power Company. Both arc and incandescents were run on the same circuit from a Brush forty-lighter, driven from the shafting of a mill about 200 yards from the building. At the concluding *soirée* on Friday, the 13th inst., a lecture was delivered by Mr. W. Kingsland, A.S.T.E., entitled "Electricity, a new Commodity." The lecture was illustrated by many experiments with the electric light, and the transmission of power was also practically demonstrated, the current which supplied the lights in the building being exclusively employed for these experiments, thus demonstrating the ease with which it could be sub-divided and applied for a variety of different purposes simultaneously. The company have, we are informed, been much complimented on the excellence of their arrangements for lighting the building.

Royal Society of Edinburgh.—At the last meeting of this society Mr. G. C. Knott, D.Sc., communicated two papers—the first "On the Measurement of Resistance of Electrolytes," in which he described a new and simple method which he had devised for obtaining rough and fairly accurate measurement results; and the second "On the Electrical Resistance of Hydrogenised Palladium," in which he communicated results practically corroborating the prior observations of Professor Dewar, that the resistance increased proportionally to the charge. Professor Tait communicated the result of some further experiments made to determine the thermo-electric position of pure ruthenium. Professor Tait said that he would now, by means of pure iridium and pure ruthenium, be able at last to form the standard thermo-electric thermometer which he had been seeking for so long, which could be reproduced everywhere, and by which comparison could be carried out all over the globe. These two metals would give them a perfectly definite standard of measurement for the purpose of comparing the temperatures, especially very high temperatures, of melting bodies in furnaces, &c., for which they had no proper instrument so far.

Electric Lighting and the Corporation of Glasgow.—At the last meeting of the Corporation of Glasgow, the minutes of the Gas Committee were brought up. Amongst other things, the minutes stated "that the town clerk had reported that the Board of Trade had issued model clauses which they proposed to insert in all Provisional Orders for Electric Lighting powers. From these clauses it would appear that the Board of Trade intended to put Corporations in very much the same position as private companies, and, *inter alia*, to make it compulsory on Corporations, as well as such companies, to undertake very serious pecuniary responsibilities. A representation against that proposal had accordingly been transmitted to the Board of Trade on behalf of the Corporation of Glasgow, as well as of several of the larger towns in England, who were promoting similar Provisional Orders, but no answer had yet been received to this communication. In these circumstances the Town Clerk advised that, in the event of the Board of Trade refusing to grant a Provisional Order to the Corporation substantially on the lines indicated in the application which had been deposited, the Corporation should withdraw their application. They would then be left free to make any arrangements they might think proper with private Electric Lighting Companies for lighting, experimentally or otherwise, any selected portion or portions of the municipal area. The committee unanimously approved of that course, and resolved to recommend to the Town Council accordingly." The minute was approved.

Another Box of Mystery.—A correspondent of the *Daily News*, telegraphing from Vienna on Friday night (April 13), said:—"Yesterday experiments were made here with a new electric accumulator, which is alleged to be much cheaper and more effectual than Faure's. The inventor is a Viennese. He dispenses with a dynamo-electric machine. A lamp which has burned since last night is still alight." This is another of those mysterious telegrams which from time to time set the public in a flutter of excitement, only to let them down with a smash when fuller and more reliable information comes to hand later on. As to the accumulator being "much cheaper and more effectual than Faure's," we fail to see anything new in this. There are several answering to that description much nearer home than Vienna. "The inventor is a Viennese." That we can understand; but "he dispenses with a dynamo-electric machine" admits of so many different readings that we must confess to being completely puzzled by it. Does the author of the telegram mean that the inventor dispenses with a dynamo for charging his battery? If so, he has evidently solved the perpetual motion problem, for we cannot suppose that he intends to imply that the inventor charges by means of primary batteries. He surely cannot mean that dynamos are henceforth to be consigned to limbo, and, if not, what does he mean? Then, again, "a lamp which has burned since last night (Thursday) is still alight (Friday)"; that is to say, twenty-four hours. What kind of lamp? And was it fed by one or more cells? The telegram is so absolutely vague, and so very likely to mislead the public, that we think it would have been just as well not to have published it.

Vienna Electrical Exhibition.—We have received the following official communication from the Science and Art Department, relating to the reduction in the Austro-Hungarian railway rates in connection with this exhibition. From this document it appears that (1), on goods sent per package the rate to Vienna and back will be 0·16 kreuzer per 100 kilograms per kilometer plus 2 kreuzers terminal charges (equivalent to a reduction of 70 per cent. on the usual rates). (2.) On goods sent per truck load to the exhibition the rate will be 0·13 kreuzer per 100 kilograms per kilometer to Vienna and back, the freight being for the actual weight with a minimum of 5,000 kilograms per consignment and truck load. (3.) The rates specified under 1 and 2 are through rates from place of receipt to place of delivery. (4.) Subsidiary charges, exclusive of terminal charges, will be according to the various tariffs of the lines concerned. (5.) Insurance of objects sent to the exhibition is granted as an exception to the usual rule on the matter. These facilities are only good during transit from Austro-Hungarian stations to Vienna and *vice versâ* and under the following conditions:—(*a*) Besides the way bill, consignments must be accompanied by a certificate issued by the exhibition committee giving the name of the sender and a list of the articles sent. (*b*) Goods are to be sent back by the route they came. (*c*) The way bill accompanying goods on the return journey must have annexed to it the way bill which accompanied them on the journey to Vienna; these two way bills must be further accompanied by a certificate from the exhibition to the effect that the objects were duly exhibited but were not sold. (*d*) There must be no charges "contre remboursement" on the goods either to or from Vienna. (*e*) The goods must go by goods train; if sent by passenger train (as express goods) the full rates will be charged. The organising committee at Vienna inform us

Digitized by Google

that small iron cases will be provided in the machine room, in which visitors may enclose their watches whilst inspecting the dynamos, &c., in order to avoid their being magnetised and so stopped.

Siemens's Regenerative Gas Lamps.—Last week we referred to a report from Colonel Haywood, engineer to the Commissioners of Sewers, on the lighting of Fleet-street by Sugg's improved gas lamps, in which he gives some figures relating to the cost of this improved lighting. In another part of the same report Colonel Haywood deals with Siemens's patent regenerative burners, which have for some time past been used to light the city end of Holborn. Referring to the report we find that the illuminating power of each lamp is stated by the company to be equal to 130 candles. No photometrical observations have been made by the Commission to test their illuminating power. The ordinary 5ft. batswing burner should produce a light equal to about 14 candles. The illuminating power claimed for the new lamps is, therefore, 9·28 times that of the ordinary lamps. The relative costs of lighting the thoroughfare of Holborn appear to be as follow:—By the ordinary system the cost of each lamp, including lighting, extinguishing, &c., was £4 10s. 4d. per annum, or a total charge of £99 7s. 4d. per annum for the 22 lamps; this is exclusive of the lamps on the urinal in the centre of the carriageway. By the new system the cost, as given by the company, is 103,200 cubic feet of gas per annum at 3s. 2d., £16 6s. 10d.; lighting, extinguishing, and maintenance per lamp per annum (estimated by company), 18s. (the Gas Light and Coke Company estimate the cost of lighting, extinguishing, and maintaining these lamps at £3 each per annum); total per lamp per annum, £17 4s. 10d.; total for 22 lamps per annum, £379 6s. 4d. The expense by the ordinary system being £99 7s. 4d., and by the improved system, £379 6s. 4d., the latter is, therefore, 3·81, or about $3\frac{3}{4}$ times as much as the former. The general result appears to be that the lighting with Messrs. Siemens's regenerative burners gives more than nine times as much light as the ordinary street lighting, and at about $3\frac{3}{4}$ times the cost.

Telephone Wires in Bradford.—We make the following extracts from a report on the over-house telephone wires in Bradford (Yorkshire), made by Mr. John Walsh, of Stretford, Manchester, to the Corporation towards the close of last year, which, though not new, is interesting. Mr. Walsh began by referring to a previous report made on the 18th April, 1882, in which he laid down certain conditions which should be observed in the erection of over-house wires. These conditions were:—"1. That wires should cross streets at right angles, and be 'shackled off' at the supports. 2. That wires should not be suspended across open spaces, but that they should follow the lines of the buildings. 3. That poles well set in the ground and stayed should be used as supports for the wires where possible. 4. That attachments to chimneys should be avoided. 5. That wires crossing streets should not be less than thirty-five feet from the ground at the lowest part of the span. 6. That spans should not exceed as a rule 100 yards, with galvanised iron wire of No. 11 gauge, this being the wire with which the existing telephone lines have been constructed," Mr. Walsh then went on to point out certain lines belonging to the National Telephone Company which did not comply with these conditions, and which required attention. The chief alterations advised by Mr. Walsh were that some of the spans—one was 200 yards long—should be shortened, that phosphor bronze wire should be substituted for No. 11 galvanised iron wire, crossings made at right angles, and poles substituted where possible for standards on buildings. These alterations were carried out by the company in such a way as to enable Mr. Walsh to conclude his report as follows:—"In conclusion, I should like to be allowed to say that so far as I have been able to see, the Telephone Company have very fairly complied with the requirements of your committee as regards the lines they have re-constructed. Phosphor bronze wire is very well adapted for telephone over-house lines, because of its lightness and great tensile strength, and I am personally in favour of it, but there has not been yet time to test its behaviour in very frosty weather, but still I am sanguine of its being all right. Its lightness is its great recommendation, because in case of breakage there is not so much danger as there would be with No. 11 iron wire."

Electric Lighting in the House of Commons.—In the House, on Tuesday night, the following interesting little palaver was carried on. To begin with, Lord R. Churchill asked the First Commissioner of Works whether the Edison Company had lighted the dining rooms and smoking rooms of the House of Commons at their own expense, free of any charge to the public; and whether he would undertake that before any further arrangements were concluded for the lighting by electricity of the Houses of Parliament, or of any part of them, the business should be open to tenders in a manner similar to all other Government contracts. Mr. Shaw-Lefevre replied that the Edison Company offered to light the library and dining rooms of the House of Commons at an expense somewhat less than the cost of the gas which would have been consumed in the same time—an amount under £100. He thought that it would, on the whole, be in the interest of members to try the experiment. There was no further obligation to the company. He proposed before the end of the Session to consult the opinion of members as to whether this system of lighting should be permanent or not. If permanent, he did not think, from his experience of electric lighting, that it was a proper subject for competition. Lord R. Churchill asked whether it was not the case that the Edison Company had, for a considerable time, been lighting the General Post Office, with a satisfactory result; and whether, before the Law Courts had been lit by the Swan Company, the Messrs. Siemens, the Edison, and other companies had tendered, but the Swan Company was selected. Mr. Shaw-Lefevre said in answer:—I received no tenders from any of the companies named. After careful inquiry I invited the Swan Company to tender, and I accepted their tender. The Edison Company had lighted the Post Office, and it was mainly in consequence of their success there that I accepted their suggestion to light the library and dining rooms of the House of Commons. Lord R. Churchill then gave notice that he would call attention to the subject on the vote for the Houses of Parliament. Viscount Folkestone interposed here with: Does the hon. gentleman intend to extend the electric light to this chamber, and will he consider the desirability of substituting the electric light for the gas lamp on the Clock Tower? To which Mr. Shaw-Lefevre replied: I have no such intention. Mr. Alderman Fowler thereupon asked the somewhat facetious question: Is the hon. gentleman aware that the light on the Clock Tower went out the other night? Though it provoked some laughter, the House were apparently left in doubt as to Mr. Shaw-Lefevre's knowledge on this point.

The Patent Laws.—On Wednesday night Mr. H. Trueman Wood, secretary of the Society of Arts, read a paper before that body, in which he dealt with the three Bills for the amendment of the Patent Laws now before the House of Commons. One is the society's own Bill, another that introduced by Mr. Anderson, and the third that brought forward by Mr. Chamberlain. The first of these, Mr. Wood

Digitized by Google

stated, had been fully discussed in that room; the second he characterised as being put forward "rather to represent the views of its originators than with any serious idea of its passing into law," and it was, therefore, wholly to the third, or Government Bill, that he directed his attention. Before analysing this Bill, however, Mr. Wood gave a sketch of what our system of granting patents ought to be. "Briefly stated," he said, "the object of a perfect patent system should be to encourage invention, by holding out sufficient, but not excessive, rewards to those who make useful inventions; to secure to the public the full benefit of inventions, both during the period of protection and afterwards; to stimulate progress in the application of all knowledge to useful purposes, by taking care that information as to what has already been effected is readily accessible; and to do all this in the simplest, clearest, and easiest fashion, at the least cost of time, trouble, and money to the inventor and to the public. Unless the present Bill can be shown to do all this—unless it is found to reach the high standard which can legitimately be applied to it—it would be better to let it follow the fate of its numerous predecessors, and to wait yet another year or two for the reform so often asked for, and so long delayed. It is the object of the present paper to try and ascertain how far the present measure will satisfy these legitimate aspirations; or, at all events, to put the matter before you in such a form that a discussion upon the Bill may afford some information to those members of Parliament who are interested in the matter, and especially those forming the Committee which has the Bill before it, as to the views of a meeting specially qualified to deal with this complicated question." Mr. Wood then proceeded to consider the different heads of the Bill, to point out its shortcomings and suggest amendments, devoting the larger portion of his paper to the consideration of "Applications for and grant of patents." In conclusion, he said:—"If I have devoted the main portion of my space to the enumeration of defects, I may remind you that the object of a paper like this is to draw attention to faults, with a view to their removal. Gratitude for favours received must be assumed, even if it be not expressed. On the whole, I think it cannot be doubted that the Government Bill is defective in many important respects, and requires careful amendment in committee. The machinery is inadequate, many parts of it would prove unworkable, and some others, it can hardly be doubted, would not work in the way which it may be assumed was intended by its framers. It is, however, certain that Mr. Chamberlain, and those with whom he has acted, are anxious to do the best they can to improve the law, and there need not, I think, be much fear but that they will listen to any suggestions for the improvement of their measure, and will give those suggestions such attention as they may think they deserve. I cannot conclude without expressing my personal indebtedness to the members of the society's patent law committee, and especially to two of them, Sir Frederick Bramwell and Mr. Alfred Carpmael."

Electric Lighting at the Manchester Exhibition.—The Members of "The Joule Club," a new scientific association recently formed in Manchester, held a meeting last week at the Manchester Electrical Exhibition, when Mr. Heys read a paper descriptive of some of the exhibits and also giving a rough outline of the principles of the dynamo as illustrated in a few typical modes of construction, the storage of currents, and the methods of distribution and illumination. In the application of electricity for general purposes, Mr. Heys said, we were at once faced with a difficulty. The current could only be distributed economically at a high difference of potential, or as it was now called pressure, but in our houses such a current would be highly dangerous. How to reconcile these requirements had puzzled many inventors. Mr. Edison had not got an accumulator of his own, and he had very lately derided their use, but as he saw Mr. Edison had a few days since taken out a patent for one of these delusions, he supposed he was beginning to think like other people. To meet the difficulty, and the certainty of a far higher pressure current in the future, a local system of distribution would be necessary. Let them suppose that their water service in the streets was laid at 700lb. pressure. It was certain that their house-service fittings would be in continual danger; but let them take the 700lb. pressure to a cistern at the top of a house, and draw the supply from the cistern, and they would be safe. Just so with electricity; substitute for the cistern storage batteries, and the parallel was complete. Of course there need not be a battery for every house, but for every convenient section. With regard to the question of safety, Mr. Heys said that if the leads or wires of a system were of sufficient capacity, there was no fear of their heating, and this was a point to be ever borne in mind. Roughly speaking, they might say that for every 800 amperes strength of current there should be one square inch of copper in the conductor. But there were other dangers besides heating the wires. If an electric light circuit were broken either purposely as at a switch, or cut out by the breaking of a lamp, or by accidental severance of wire, an arc would be formed capable of firing some substances. This might be prevented by care to some extent, for example, by using safety switches or cut-outs, and by employing care in the erection of the lines. For this work none but competent and experienced men should be employed. Circumstances might, however, very easily arise, as, for example, from short circuiting or an accidental joining over of the lead and return wire, or from the sudden turning off of a considerable number of lamps, when the amount of current will be too great for the safety of the lamp, if not for the conductors. To meet this, safety plugs of lead wire were employed. These melted quickly under the heat of the increased current, and so broke the circuit before any damage could be done. Taken altogether, he maintained that there was very much less danger with a good electrical system than with gas, and far more satisfaction. Having entered into a detailed comparison of the Swan and Edison lights shown in the exhibition, Mr. Heys called attention to several exhibits shown by Messrs. Pike, Sanderson and Pike, including an electric exploder for firing shots in mines; a signal for mines by which an alarm could be sounded simultaneously at both ends of the circuit by any one in the galleries of the mine simply pressing together two wires, and an apparatus by means of which engines could be stopped at once from any part of the works. In conclusion, Mr. Heys briefly touched upon the subject of electric motors. A dynamo electric machine, he said, when it was included in an electric current derived either from a battery or from another dynamo would revolve its armature rapidly, and drive any suitable mechanism with which it might be connected. Of course they might easily understand that a little rearrangement of the brushes was required to give them the necessary amount of lead, because, when driven by current, or, more properly, when driving, the armature revolved in the opposite direction. He exhibited two types of motor, the Griscom and the De Meritens, which were employed driving appliances in the exhibition—one in connection with a mechanical stoker and the other a sewing machine, and both actuated from the storage batteries of Electrical Power Storage Company.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XX.

We have now to consider the operation with reversed charges alluded to in the last number, without which the use of the electrometer for measuring insulation resistance would be imperfectly treated. We have thought it necessary to give two or three examples of this kind of test, and shall take the opportunity of carefully explaining the principles at work, believing that the matter to be gone over in this part of the subject will furnish opportunity for getting a clear insight into details and points which are likely to occur in other branches in practice, about which learners are often confused, not understanding the principles on which they act mechanically. The test now before us is illustrated in Figure 43, where we have the connections necessary for its operation. We have a double current battery key for sending different charges to line (or cable), also a slide resistance scale with one battery pole at each end, as in the last test, and one end to earth; the lead from this arrangement connects with another double current key, which is necessary for reversing the connections with the electrometer quadrants when the battery key is reversed; the cable is joined to either bar of this key when the adjacent plug

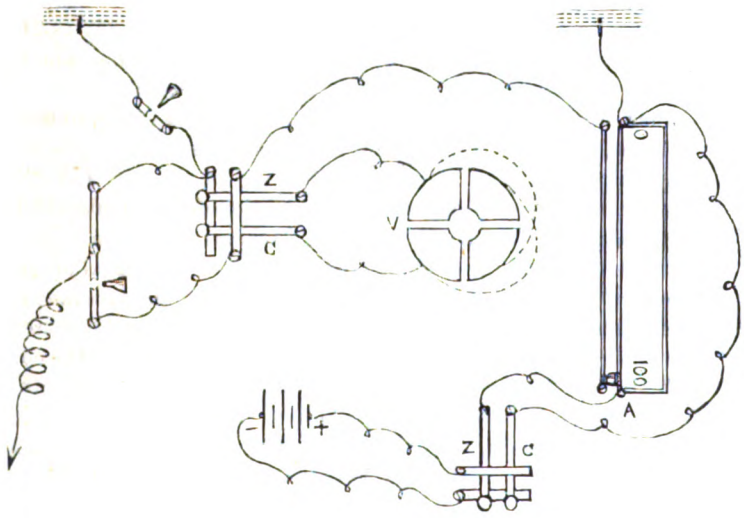

FIG. 43.

is inserted. This plug answers the purpose of bringing the cable and both pairs of quadrants under the influence of the charge when in its place, and when removed leaves one pair connected with the cable and the other with the battery. The cable can be put to earth if required by the other plug, and the electrometer can also be earthed by a third plug not shown in figure. The arrangements might have been varied, but we have here a plan of connections used in practice for a considerable time, and one which was found to answer all requirements perfectly well. It will be noticed that we have a slide resistance, whilst in the previous test we had a set of coils without a slide and scale. Either plan will answer both purposes, the difference being compensated for by an alteration in the other appliances. In the present operation the inferred zero would be taken by pushing the slide down to figure 10 on the scale, when the potential of the charge would be one-tenth of the whole. We have marked only two places at the several extremities, the potential when the slide is at A being 100, and decreasing down the scale to 0. The slide takes up and conveys to line through the lower bar the potential at whatever place it may be fixed, as the charge passes to it through whatever number of resistance coils are marked off. The two keys are similarly marked Z and C, directing the change of battery poles for charging the cable and the alternate pairs of quadrants. One hundred cells will be used, and it is very desirable to give attention generally to the state of the battery, which should be well insulated by hanging shelves or insulating trays or feet to the stand, and kept clean and free from damp on its shelves and the surface of its jars. It is assumed that the cells are all equal. The spot of light will be made (by using the micrometer screw) to fall on the end of the scale next the operator, supposing the electrometer to face it, so that the former is at right angles to his position at the table. This applies to both of these tests. As regards the limits of time fixed for the reading of the deflection, there is some difference. In the previous test we supposed the state of the cable to be noted after two minutes' total leakage; the close of the 30 seconds completed the two-minute test; and a five-minute test is also often taken in the same way by merely allowing the cable to continue leaking after the two minutes till 4′ 30″, when a reading is taken, and again 30 seconds later. In this reversal operation the cable is first charged, say with zinc, for 15 seconds, and then allowed to leak for a shorter period than 90 seconds, and after one or two readings at short intervals the charge is reversed, and a repetition of such charges is made for a certain time fixed by the electrician in charge. We do not think we ought to go through the test exactly as it has been done in practice; that is to say, as regards the particular intervals and periods of reversals. It is one devised by Sir William Thomson for his own testing room in the case of a well-known cable, and we do not like to publish it without his express permission. It will be quite sufficient to give an imaginary set of periods for charge and leakage, and, as bearing on a practical operation, the course may be usefully followed, though the details are not the same as Sir W. Thomson's.

The inferred zero will first be taken (with both positive and negative currents if desired) by using the slide as above suggested and multiplying the reading by 10. This should be done before joining up the cable, which latter (arrow pointed) will now be connected at the bar and the plug inserted. It is best to commence charging at the full minute, and, if there is no stop watch at hand, to start at 5, 10, 15, &c., minutes past the hour. We will first clamp down Z in the electrometer key, and then do the same with Z in the battery key, the slide being close up at the battery end, as in the figure. The negative charge now enters (technically speaking) the cable and both sets of quadrants. After 15 seconds the plug is taken out, when the cable and one pair of quadrants remain connected together but free of the battery charge, and the other pair continues under charge. We will suppose the cable to leak for sixty seconds; we then read the deflection, and again after one more minute's leakage; we then replace the plug and proceed to reverse. In so doing we must first release Z in the electrometer key and at once clamp down C, and then do the same with the battery key, but noting the time so as to charge the cable with the opposite charge for fifteen seconds. After this period the plug is again removed and readings taken at the same intervals as with the zinc charge. The operations can be repeated as often as may be necessary, and at the end of the test the cable will be put to earth or removed, the keys being first released, and the electrometer also put to earth if required. The object of the electrometer key in the test in one respect is for securing the passage of the spot always in the same direction along the scale, which can only be done by alternating the charge in the quadrants. We shall not go further into this particular test, but may observe that the learner should particularly avoid being flurried or over anxious about the passage of time, as regards the intervals between reading and charging, &c. Beginners at this work always imagine the seconds pass much faster than they really do, and from uncertainty in this matter work themselves up into a state in which they lose their presence of mind, and miss the readings altogether. It surprises them after a little practice to see how much can be done in even 30 seconds. They may learn the value of time in this way, if they gain no other advantage.

We will now turn to the working out of this kind of test, whether taken with the electrometer or the galvanometer, though, perhaps, more particularly with reference to the former. At the close of the last number we stated that the test was independent of the length of the cable. This would refer to the resistance per unit of length or knot. The calculation can be made either way, using either the capacity per knot or the total capacity in the working out. Let us look at the matter a little closer than we have yet done. If our operation is made with reference to a knot-length of the cable under test, all the conditions are taken in relation to this length. We have also the conditions of capacity to consider, that is, the charging capacity per knot of this particular cable. In connection with this is the specific capacity of the insulating material, since insulators differ in this respect according to their nature. But unless one kind of insulator is to be compared with another, we need not regard this point in what we are now doing. The condition is involved in the value for capacity which we employ in the formula. The reader will see clearly why the quality of capacity forms one of the conditions governing the calculation of the insulation resistance, because the action resisted is between two opposed conducting surfaces (the copper conductor and the sheathing or earth) and the accumulation must influence the state of affairs favourably or otherwise as it is great or small. Now we have a body, that is a cable of a certain charging capacity charged to a certain potential, or charged to an extent which we have estimated by the number of divisions on a scale which the charge would cause its index, the light, to pass over if all ran out. We may say that the charge was one that would embrace a sweep of 4,875 divisions. It will be remembered that this is the first of the two boundaries, so called in our last number, between which we have an interval of 30 seconds. This amount, then, we may call the potential of the cable at the commencement of this period. The cable loses its charge gradually and falls in its potential from 4,875 to a potential represented by 4,825 in 30 seconds. This discharge takes place against or through a resistance (every action or effort is one opposed by a resistance) which is that offered by the dielectric separating the conductor inside from the earth or water outside. This resistance in the first place will vary directly with the time during which it is in force, or, in fact, during which we limit its consideration. The longer it acts the more of it there is. It will vary *inversely* as the charging capacity of the cable which would, as before suggested, favour the condition through the dielectric—the greater the charging capacity the less the resistance, and *vice versâ*. We have further to consider the rate of discharge, which is a ratio that is also *inverse* to the resistance under notice, because the faster the cable discharges the less it affords resistance to discharge, and therefore the percentage of leakage holds the same relation to the resistance that is given by the capacity. This statement is to be taken as *generally* true, that is to say, it is a part of the truth the exactness of which is expressed by an addition to it. We will endeavour to explain the apparent anomaly by reminding the student that we have to specify the conditions we are discussing by representing them as values. The percentage of discharge is truly a ratio, but when we come to apply it as a value, we must take it, not simply as a ratio, but as the logarithm of a ratio. This point in the conditions governing the formula is the only one now presenting any difficulty, and must be briefly examined.

Of course, the reader knows that compound differs from simple interest in the fact that the interest at each term is calculated on the sum of the capital added to the previous interest, as, say, the interest on £100 is 5 per cent. per annum. Then £5 is the interest for the first year. This is added to the £100, and the second year the interest is 5 per cent. on £105, and so on. Take the converse of this, and suppose 5 per cent. to be deducted every year on the principle of compound interest. Then out of £100 £5 would be deducted the first year, and the balance £95 is the sum on which the interest is calculated for deduction the second year. It is in analogy with this latter course of operation that we find the fall of charge in a submarine cable. For, as stated above, if 5 per cent. of the charge escapes in the first minute, 5 per cent. of the remainder would escape in the second minute. The resistance of the cable is small or great as the rate of interest is high or low; and, as in a money transaction, it may be estimated as favourable where the accumulation is rapid, because the amount in each year is much increased. So with a cable, it is a good one (in the sense of being well insulated) if the amount is but slowly *decreased*. We have the capital, the rate of interest, and the amount. We have already suggested the illustration of the escape of water from a cistern. The ratio $\frac{800}{400}$ then mentioned gives in reality the rate of interest—if the amount at the first period is double that at the second 50 per cent. has escaped. Returning to the money analogy, the amount of £100 may be taken to represent the first reading, and £105 the amount or principal at the end of the year for the second reading. Then the ratio $\frac{100}{105}$ represents the rate of interest, for the original capital is increased by £5, or one-twentieth of its amount, and as 100 : 105 :: the capital : $\frac{100}{105} = \frac{20}{21}$, and 20 is increased by one part. The case of the cable losing its charge is the converse, and the ratio, composed of two readings subtracted from zero, gives us the rate of interest which could be expressed in percentage form. Thus the ratio $\frac{4875}{4825}$ is the exponent of the rate of decline of the charge, as the ratio $\frac{100}{105}$ declared the rate of interest in the money example. Now we took the fraction $\frac{20}{21}$, and found the rate of interest by seeing how many units more there were in the denominator than in the numerator; it is one-twentieth, or 5 per cent. In the cable fraction the denominator is the smaller because the operation is a decline instead of an increase. There are 50 units out of 4,825, and this is for the half minute; it amounts to about 3 per cent. per minute, an imaginary quantity not claiming to be the true standard for cables.

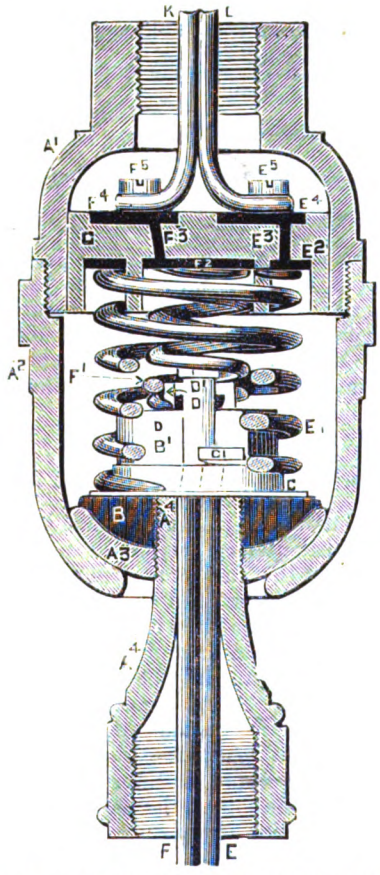
The only point now remaining is the fact of using the ratio or $\frac{P}{p}$ as a logarithm, and the actual proof by figures is out of our province, but to any reader who may not be acquainted with the rules for calculating compound interest, we can only say that the terms of this ratio correspond to the amount and principal in that calculation, and in the course of making a rule for general application, in which algebraic symbols are employed, the relation or inter-multiplication of these results is a combination which can only be correctly expressed by a logarithmic statement. Then, in working the formula given in a recent number, the insulation resistance will be obtained in this way. As several different cables are tested every day, and each will probably have a different capacity per knot, every device which minimises the labour of calculation is desirable. The capacity forming a part of the formula $R = \frac{26{\cdot}06 \times t}{F \log \frac{P}{p}}$ and having to be divided into the numerator, there would be a succession of calculations, but a constant value is found for each cable, which has only to be divided by the $\log \frac{P}{p}$ to give us the resistance per knot in each case. The value 26·06 is constant, as is also the 30 sec., the time can be worked either in seconds or minutes—the latter is preferable, therefore the value for t will be ·5. That for F, the capacity per knot, will vary in each cable. We will suppose a figure, say, ·333. Then 26·06 × ·5 and ÷ ·333 will give us a constant for that particular cable. It is usual to work by logarithms, which can very easily be picked up by those who are not acquainted with their use. From the logarithm of the constant will be subtracted the

Digitized by Google

logarithm of the log $\frac{P}{p}$, and in working out the beginner must be careful to put always the characteristic to the logarithmic value, and in re-converting the logarithm to its natural number to render the figures correctly. Also not to forget that the ratio $\frac{P}{p}$ is already a logarithmic value. In using it we must first find the logarithm of P, and from this subtract the logarithm of p. The result is a logarithm, of course, but we must treat it as a natural number and find its logarithm again, then subtract this from the logarithm of the constant. The full natural number of the remaining logarithm is the insulation resistance per knot in megohms of the cable. In the article on the working out of tests we shall furnish an example of this, as of other calculations.

VERITY'S CUP AND BALL JOINT FOR ELECTRIC LIGHT PURPOSES.

We are glad to see the manufacturers of gas fittings turning their attention to the requirements of the electric light. Messrs. Verity and Sons were amongst the earliest, if not the earliest, of the manufacturers to recognise that business is

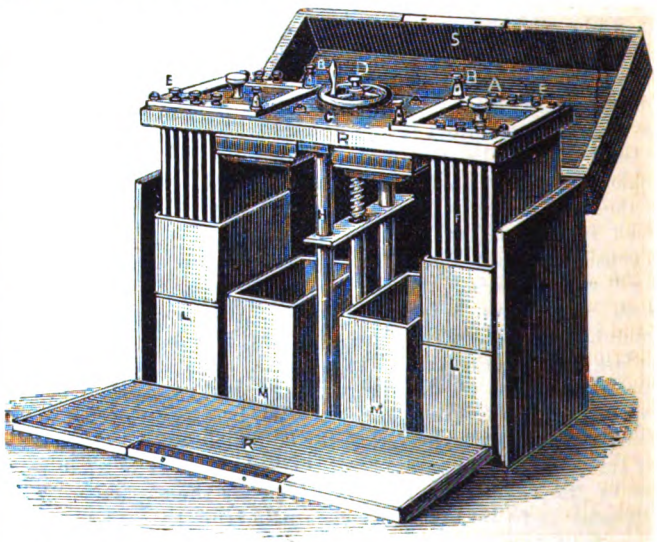


Verity's Cup and Ball Joint for Electric Light Purposes.

not exclusive, and that the practical knowledge already obtained might be of great service in designing apparatus for the newer industry. They, therefore, attempted to make themselves conversant with the requirements, with what success is known by the general appreciation of their productions at the Crystal Palace last year. A more recent introduction is the cup and ball joint, which we now illustrate. The parts A^1, A^2, A^3, A^4, shown in section, are similar to the usual ball and socket arrangement, the part of the ball A^3 rotating in the cup A^2. On the end of A^4 is screwed a piece of vulcanite, B B^1, for insulation, to which the rings C D are fixed. The insulated wires E F from the electrolier are carried through the tail piece A^4 to the rings C D, and contact with them is made by the screws C^1 D^1. The two helices E^1 F^1 are made to tighten on to the rings C D respectively, and to make good contact with them. All the parts where good electrical contact is required are turned over to prevent bad contact from oxidation of the parts. The tops of these helices are flattened and press against the plates E^2 F^2 fastened to the vulcanite part G. These plates are again connected by the conducting wires E^3 F^3 to plates E^4 F^4 respectively. To these latter plates the insulated wires K L are brought through the neck A^1, and connected by means of the screws E^5 F^5. From this it will be seen that when the electrolier is swung the flattened top of the helices are always electrically connected with the plates E^2 F^2. Experience has taught the necessity of using a metal for the helices having somewhat the springiness of steel and the conductivity of copper, and, after a number of trials, phosphor bronze was found the most suitable metal for the purpose. The various parts are all carefully tested before leaving the factory, and a safe margin allowed in the construction for the current it is proposed to carry. A considerable number of these joints are in use, and found to act satisfactorily. As we have said, Messrs. Verity and Sons have given great attention to electric light fittings, have recently produced various improvements in such apparatus, and have shown sufficient confidence in the value of the light to have it installed upon their premises in Covent Garden, and we have no doubt they will be able to produce any kind of fittings the increased adoption of incandescent lighting may demand.

A PORTABLE BATTERY FOR MEDICAL PURPOSES.

The following form of portable battery for medical purposes has recently been devised by M. Chardin, a French



Portable Battery for Medical Purposes, designed by M. Chardin.

electrician. It is an ordinary bichromate battery, the zincs and carbons of which are fixed to a movable frame R, and so arranged that they can be inserted partly or wholly in the liquid, or removed therefrom as required. As will be seen on referring to the illustration herewith, the movable frame is raised or lowered by means of the screw D and its handle C, the guides H keeping it in position. When the battery is not required for use, the movable frame is raised until the plates are just clear of the top of the jars L. These are then put where the ebonite jars M are shown to be in the figure, and the jars M are placed where L are. The movable frame is then lowered, the plates going into the empty jars M, and the tops of the jars L, which contain the exciting liquid, being closed by the india rubber stoppers shown on each side of the letter R. The side facing the reader is then shut up, the lids clapped down, and the battery ready to be carried away. There are three zinc and four carbon plates in each jar, connected in multiple arc. B B and E E are the terminals connected with the plates.

LITERATURE.

Electric Light: Its Production and Use, Embodying Plain Directions for the Treatment of Voltaic Batteries, Electric Lamps, and Dynamo-Electric Machines. By J. W. URQUHART, Electrician. Edited by F. C. WEBB, M.I.C.E. [Crosby Lockwood and Co.]

We have an intense dislike to the notice of technical books where a living author calls in the aid of an editor. Which of the two is to be praised for satisfactory work, and which is to be blamed for unsatisfactory work are questions we are unable to answer. Some years ago, during a conversation with an intimate friend, a partner in one of the leading publishing firms, the conversation glided into remarks upon successful books from a publisher's point of view. A special book was named as an example of a book compiled by a man whose ignorance of the subject was clearly shown by every page, whose correct paragraphs were simple transcriptions without acknowledgment from other authors, and who was evidently incompetent to decide which was correct and which was incorrect when both data lay before him. The book was attractively arranged by the printer, well printed, well bound, and issued at a low price, for all of which mercies it was said no thanks were due to the author. The book was said by the publisher to sell better than any other of the hundreds this firm published. The reason given for its extensive sale was that purchasers, being utterly ignorant of the subject, were induced to purchase by the look of the book.

The book before us is not a cheap book, yet one edition has sold. It is well printed, and presents an attractive appearance; but far be it from us to hint that its success is due to these features. A work of this kind — we write subject to correction — seems to require no author, only a competent editor. There is a minimum quantity of original matter, and a maximum amount of "edited" matter. In fact, it seems that the sole value of such a work — and this value is really considerable — is in the manner in which diffuse information to be found in papers to societies, in periodicals, &c., is condensed and edited. Theory is carefully avoided, but a concise description of all the well-known pieces of the electric light apparatus is to be found herein. This to us is the sole value of the work. Any one interested will find a short account—an account requiring no mental strain of the reader to understand—of the electrical productions for the last few years. Discrimination has been shown in the method of obtaining information, the sources to the initiated being easily traced—many, in fact, being duly acknowledged—and greater discrimination has been shown in the selection of Mr. F. C. Webb as editor. Some of the objectionable features of the first edition are found wanting in the new edition, but we yet think that sentences like the following in a work of such pretensions should be left out:—"The price of these machines, with the exciter, is from £170 to £535." Is there anything similar to this in "Rankine," or "Clerk-Maxwell," or "Tyndall," or generally in books claiming to be out of the class "price lists?"

We do not wish to be thought condemning books of this kind; our idea is that such works are valuable, but their value is not quite so high as the published price of this work implies. If we are asked to pay so much for second hand material, no matter how well compiled and edited, what is the value of a similar sized work which is the outcome of brain power in the shape of original thought? We have enough books containing mere descriptions, and we begin to ask, when is Professor Ayrton's promised book or Mr. Gordon's promised book to make its appearance?

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending the 13th April, 1883, were £3,792.

MAGNETISM.

BY JOHN T. SPRAGUE.

(CONTINUED FROM PAGE 528.)

11. *Magnetic Field.*—It is of great importance that this conception of a "field of force" should be thoroughly realised and replace the old fallacy of a repulsive *force* because this supposed force is very apt to mislead in many directions, and it is well to see that throughout all nature we find no trace of a repulsive force, and, therefore, ought never to apply the idea to any phenomenon merely because it offers an explanation. The action of magnets is the strongest apparent evidence for the existence of such a force, and this makes it the more desirable to show that no such force is necessary to explain the facts. Fig. 9 will convey the idea of a magnetic field, in end view and perspective. It shows the magnetic bar constituted of the annular (or spiral) systems of statically polarised molecules as in Fig. 8. These molecules manifesting magnetic force at right angles, and their actions uniting in the aerial line of the magnet and developing the lines of magnetic force as shown in the arrows; the external "field of force" is developed, under the general law of inductive action by circles of polarisation in the opposite direction to those of the magnet itself; the magnetic lines of force of these therefore attract, and form closed lines of force with those of the magnetised bar. The external arrows therefore show the position in which another magnet would necessarily place itself, *because in so doing the lines of force of the second magnet would place themselves in those of the principal field.* The lines of force of magnetism, like those of electricity, tend to the direction of most capacity, so that whenever a magnetised or magnetic body enters the field, the lines of force concentrate within it, and the external actions are to that

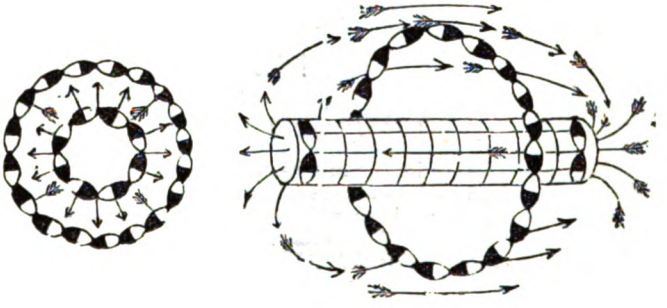

FIG 9.

extent suppressed. This is just what happens when an armature is applied to a horse-shoe magnet. In the case of a horse-shoe the external field forms itself in the space around the opening, forming an ellipse, with its circles of polarisation in the same order as those of the magnet (instead of reversed as in Fig. 9 where the magnetic lines have to return on themselves); on the approach of the armature the lines of force are taken up by the iron, which becomes itself a magnet forming a continuation and completion of the horse-shoe; the energy of the external field develops the force of attraction, and if the armature is sufficiently large and in very good contact, the magnet now ceases to have any external action, because its whole circuit is self-contained. This never occurs completely in the case of an armature, because perfect contact is not to be attained; but if a homogeneous ring of steel were magnetised it would show no external magnetic action. Such a ring would manifest opposite free poles of equal strength, at any point in which it might be cut across, and part of its energy would pass into the external circuit which would be then developed.

12. *Attraction and Repulsion.*—When the magnets approach each other they manifest *attraction* between unlike poles N and S and *repulsion* between like poles N N or S S. When a non-magnetised but magnetic body approaches a magnet it is always attracted, because magnetism is *induced* in it as just described in true polar order. If a weak magnet approaches a strong one, its magnetism may be overpowered by induction, either temporarily or permanently. *Repulsion*, however, is not due to any repulsive force between the poles; as with electricity, it is simply the reactions of the whole fields on each other and the endeavour to place themselves symmetrically.

Attraction is illustrated in Fig. 10, which shows the action of opposite poles approaching; the lines of the magnet and external fields of 1 and 2 enter each other and blend in one; they draw together just as do opposite electric charges, and the result is

Digitized by Google

that the two magnets constitute one long one, in which the S N poles at the middle disappear, and their forces are transferred

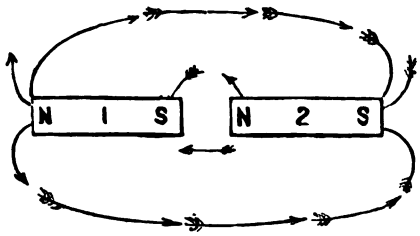

Fig. 10.

to the external poles, as when two Leyden jars or galvanic cells are coupled in series.

Repulsion is explained by Fig. 11, where 1 and 2 are magnets with like poles presented; at once the lines of 1 S and 2 N coalesce and tend to turn the magnets round, as will be readily understood from the drawing. If motion is only possible in the vertical line as shown, the magnets will recede from each other,

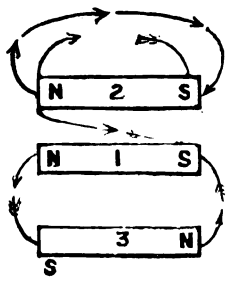

Fig. 11.

because each of them seeks to take possession of the molecules of surrounding air to complete its field, and therefore the magnets themselves move in the direction which involves the least resistance. Fig. 11 shows also another instance of attraction as between 1 and 3, where both poles act together, and each bar acts as the external field of the other.

13. *Mechanically Produced Fields.*—Fields of force such as are shown in these figures are not merely imaginations; they are capable of being visibly produced by mechanical means, and in them may be reproduced phenomena strongly resembling those of attraction and repulsion. The curious vortex rings formed of smoke issuing from an opening in a chamber subjected to a sharp blow (and resembling those often produced by cannon) are to some extent illustrations of this, for these circling rings possess many of the attributes of solid bodies, moving as a connected whole in space, and even rebounding from each other.

Dr. C. A. Bjerknes, of Christiania, exhibited at the Paris Exhibition of 1881 a series of experiments in which the motions of attraction and repulsion were very perfectly imitated by means of currents of water. The apparatus consisted of small drums connected to an air-pump which alternately expands and contracts the diaphragms. To give any intelligible explanations of the interesting experiments would occupy several pages, but the result is that if two such drums are placed in water so that one of them is movable, and a succession of pulsations imparted to the diaphragms, *attraction* occurs if both pulsate alike, but *repulsion* occurs if the pulsations are alternating.

Mr. A. Stroh, in a paper read to the Society of Telegraph Engineers, 27th April, 1882 (and which received the rare honour of repetition) illustrated the same principles applied to vibrations in air. His paper will be found in Vol. XI., p. 192, of the *Proceedings of the Society*, and in *The Electrician*, Vol. VIII., pp. 405 and 421, with numerous illustrations showing the effects produced. These show just such "fields of force" set up by pulsations in the air as are shown by iron filings in the case of magnetism.

14. *Laws of Magnetic Force.*—Many attempts have been made to fix the laws of attractive force of magnets, and the result appears to be that it varies inversely as the square of the distance, as it must indeed from the cause which generates this universal law of actions proceeding from a centre, this being a necessary consequence of the fact that the areas of spheres increase in that ratio; but this only applies to each point of a magnet regarded by itself. Practically no distinct law can be laid down, as the force is a compound action. It is not governed merely by the distance of the attracted body from the magnetic poles, but by the form of the acting "field of force" between the poles. It is, in fact, quite possible to make a number of magnets, all of equal power upon an armature in contact, yet all differing in their attraction for their armature at different distances.

15. Let us conceive two such magnets: A (N——S) with 1in. between its poles; B (N——S) with a space of 3in. It is evident that the field of A will be the more intense, but that it will extend only a small distance from the ends of the magnet; necessarily, therefore, the force of attraction on the armature will diminish much more slowly, as distance increases, in the wide magnet B than in the narrow one A. The real law is to be found, not in the distance of the armature, but on precisely the same principles as govern the relations of two derived inductive circuits in electricity. The magnet has, in fact, two circuits in which to close its lines of force. Fig. 3 makes this clear (*Elec.*, April 14, p. 526). If we consider N and S to be the polar extremities of the horse-shoe magnet, the magnetic field is shown by the curves, it being formed on the same principles as the electric field If we now imagine a bar of iron approaching from above, this, by its greater magnetic capacity, will draw the lines into itself, and two fresh fields will form between its extremities and N and S. It is evident these two fields are a pair in series, dividing the force with the original field in *the ratio of the several capacities*, which may be roughly considered as represented by the relation of the distance between N and S as against the sum of the distances N armature S. Here again it becomes obvious that no law based upon the mere distance of the attracted body without considering the form and conditions of the magnet, can possibly express the facts and forces.

It would seem, therefore, that it is a mistake to bring the poles of horse-shoe magnets near together; that they would do more work if the opening is wide, because when once in contact the length of the armature offers small resistance, if it be made of pure soft iron, while this form gives greater range of work.

The force exerted by a magnet holding up a weight is measured in dynes by multiplying the weight in grammes by g, the force of gravity at the place, which is about 9·81 in England.

16. *Magnetisation.*—Steel may have magnetic power developed in it by drawing a bar magnet along its several surfaces, always in one direction; it is still better to arrange a complete system of bars forming an octagon or square, and draw the magnet round and round, always in one direction. In this plan the bars may be all steel, or alternate steel and iron.

If the operator has two bar magnets, an excellent plan is to place them with opposite poles together over the middle of the bar to be magnetised, and then to draw them slowly asunder to the ends, repeating this six or eight times on each face. This process is still more effective if the ends of the bar rest on two

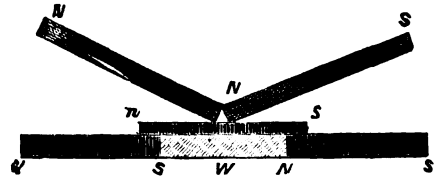

Fig. 12.

other magnetic bars with their opposed poles in the same direction as the moving magnets. Fig. 12 shows this process, N S being the bar to be magnetised and W a piece of wood to support it and steady the lower magnets. This is called the method of single touch, and is best suited to thin needles and bars not more than a quarter-inch in thickness.

The method of double touch may be illustrated by the same figure.

The triangular space between the two movable magnets is filled with a piece of wood, and their upper ends connected by a bar of soft iron, and both are moved to and fro along the bar N S, without separation. This process gives more magnetic power, but is apt to be irregular and to produce *consequent points*.

Horse-shoes should be magnetised on the same system: closing the poles with a soft iron armature, or a bar magnet properly placed, or two can be arranged facing each other.

The bar magnets may be advantageously replaced by electro-magnets which can be given a much higher specific magnetism than steel can retain; this is a great advantage because the magnet can generate no higher intensity than it possesses itself, and, therefore, the stronger they are the better they magnetise.

17. *The Battery Process.*—This is the most convenient. It consists in making the steel bar act as the core of an electro-magnet for a few seconds. A short coil should be made of stout

Digitized by Google

covered wire, the central opening of which is large enough to allow it to be passed over the bar. It should be arranged at the middle of the bar, and connected to a battery sending a powerful current through it, and regularly passed along the length both ways several times, allowing the ends to half enter the helix, and brought back to the middle before the current is stopped. The action is facilitated by slightly tapping the magnet during the process to produce vibration. It is also found that an intermittent or breaking current is more effective than a continuous one.

The magnetising is also assisted by completing the magnetic circuit externally with soft iron. In this case also the magnetism retained is higher than if the steel is not provided with an armature to complete the magnetic circuit. The reason is that as in compound magnets, part of the lines are apt to return within the mass of the metal.

AN EPISODE IN THE EARLY HISTORY OF THE TELEGRAPH.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.

[We have been favoured with the following advanced sheets of a work which Mr. Fahie is getting ready for the press. It will treat of the history of signalling of all kinds from the very earliest ages down to the year 1837, the date of the practical introduction of the electric telegraph by Cooke and Wheatstone. Mr. Fahie requests us to say that he will be glad to receive communications or suggestions from any of our readers, as he is anxious to make his history as complete as possible.—ED. *E.*]

Twenty-five years ago, in the course of a research amongst the imperial archives at Paris, M. Edouard Gerspach, of the French Telegraph Administration, discovered some documents which, in our eyes, are of exceeding value as establishing for La Belle France the honour of the invention of the first step-by-step, or A.B.C., telegraph. These precious papers were embodied by M. Gerspach in a memoir for the *Annales Télégraphiques* for March-April, 1859, pp. 188-99, to which we are indebted for much of what follows in this article.

Jean Alexandre was born at Paris, the natural son, it is said, of Jean-Jacques Rousseau. He had the education of a mechanic, some say of a physician, but his actual career was truly a faithful image of the troublous times in which he lived. In 1787 he was at Poitiers, following the trade of gilder, and as he had a fine voice he sang in the churches, which added somewhat to his slender emoluments. But soon the revolution came to Poitiers, and swept away the *clientèle* of the poor gilder and carver. His occupation, like Othello's, was gone. He went to Paris, and there maintained himself for a while by singing in the choir of St. Sulpice; but the revolutionary tide followed him, and closed the doors of St. Sulpice as of all the other churches, leaving Alexandre high and dry again, without the means of subsistence.

Feeling there was nothing else to be done, he now took to politics, and, after the manner of the times, soon found himself president of a section of the Luxembourg (club), and later on a deputy of the Convention. This latter honour, however, his simple manners made him decline. But greater honours still were yet in store, and as he was preparing to return to his workshop at Poitiers the Government sent him thither, but with the exalted rank of Commissary-General of War. Later on he was promoted to be chief of the military division of Lyons, where he had to organise an army of 80,000 men. With the title of Chief Agent of the Army of the West he next went to Angers, where, from the forty-two departments that were under his orders, he had to raise another army of 200,000 men (!). With all this greatness, he still was not happy; he yearned for a quiet life—a feeling which seems to have grown daily stronger with him, until, at last becoming irresistible, he quitted honours and politics, and returned to his home at Poitiers, as poor as he had left it—a fact, by the way, which speaks volumes for the integrity of his character.

Here we find him in 1802 producing his *télégraphe intime*, or secret telegraph. He wrote to Chaptal, Minister of the Interior, acquainting him briefly with the discovery, and asking assistance to enable him to go to Paris and exhibit his machine to the Government. The Minister asked (and naturally) in the first place for full particulars and plans of the apparatus, but Alexandre declined to divulge his secret, and addressed himself next to Cochon, Prefect of Vienne, offering to make an experiment before him. The Prefect, agreeably impressed with the conversation of the inventor, whose quick and vigorous imagination he found to contrast singularly with the simplicity of his demeanour, granted his request, and accordingly on the 13th Brumaire, year X (early in 1802) he went, accompanied by the chief engineer of the department, to Alexandre's house. The experiments were crowned with unhoped-for success, and the Prefect drew up a report for the minister, Chaptal, of which the following is the substance:—

"We were conducted into a room on the ground floor, in the centre of which we found a box nearly 1·5 metre high, and about 30 centimetres broad and deep. This box was surmounted by a dial, around which were traced all the letters of the alphabet. A well-poised needle or pointer travelled round the circle at the will of a distant and invisible agent, and stopped over such letters as composed the words that he wished to communicate. The completion of each word and phrase was indicated by an entire revolution of the pointer, which in its normal state of rest always occupied a certain determined position (corresponding, no doubt, to our zero).

"A correspondence was established between the (distant) agent and ourselves, and the success was all that we could desire. The dial repeated exactly all the phrases that we had dictated, and the (distant) agent added some from himself, which we had no difficulty in understanding. On asking why the second box was situated in an upper story, about 15 metres distant, instead of being placed on the same level as the first, the author replied that it was to show that difference of level had no effect on its action, and that the conductors could in every case go up and down, and adapt themselves to the inequalities of the ground.

"We understood, without, however, his distinctly saying so, that the author derives his power (*usage*) from some fluid, either electric or magnetic. He told us that in the course of experiment he had met with a strange matter or power, of which, until then, he had been ignorant, but which, he was almost tempted to believe, is generally diffused, and forms, in some sort, the soul of the universe; that he had discovered the means of utilising the effects of this power, so as to make them conduce to the success of his machine; and that he was certain of being able to propagate them with the celerity of light, and to any distance that may be required."

In concluding this report on the invention, which the Prefect characterised as a work of genius, he urged that Alexandre should be called to Paris, at the expense of the State, in order that he may repeat his experiments under the eyes of the Government. The minister, Chaptal, did not, however, regard the discovery at all so favourably, evidently imagining it to be a telegraph of the Chappe or semaphore kind, and wrote to the inventor's agent, declining to have anything to do with him. Such a rebuff would have acted as a *quietus* to ordinary people; but inventors are proverbially a tenacious race. Alexandre was an inventor, and, firm in his convictions, he quitted Poitiers, and in hopes of better fortune, betook himself to Tours.

There, at his invitation, General Pommereul, Prefect of the Department of the Indre and Loire, and the mayor and officers of the city of Tours, assembled at his house to assist at a public trial of the apparatus. As before, one of the machines was on the ground floor, and the other on the first story, separated from the lower room by an ante-chamber and a small court. The Prefect dictated the phrase, "Genius knows no limits," which was transmitted to the distant end, and thence returned with all the success imaginable. The next phrase, "There are no longer miracles," was repeated with the same result, and many others followed, in which all the words were reproduced by the machines, letter for letter, with the greatest exactness.*

* The *English Chronicle* newspaper of June 19-22, 1802, has a short account of these experiments, concluding as follows:—"The art or mechanism by which this is effected is unknown, but the inventor says that he can extend it to the distance of four or five leagues, even though a river should be interposed."

(TO BE CONTINUED.)

VICTORIAN TELEGRAPHS.—According to the latest statistics to hand concerning the colony of Victoria, 135 miles of line were added to the telegraph system there during 1881, and 607 miles of wire. The number of telegrams which passed from Victoria to European and Asiatic countries and *vice versâ* during the same year was 12,168, the cost to the senders being £82,211. The average time occupied in the transmission of messages between Australia and England during 1881 is stated to have been three hours and 15 minutes.

„ Labuan, Persia, Aden, Mozambique, Zanzibar, India, China, Japan, Borneo, Java, Philippine Islands, and New Caledonia	6 1	12 1	24 2

P.O. Orders to be made payable to JAMES GRAY, *at West Strand Post Office.*

ANSWERS TO CORRESPONDENTS.

C. TOWELL.—*You had better apply to the Duplex Electric Light Company, of Leicester-square, W.C., who are the makers of the batteries.*

PERPLEXED.—*We fear a short explanation will hardly help you. The result which perplexes you is a direct outcome of the fundamental laws of magnetism. If you read carefully the short chapters on magnetism now appearing in our columns you will, we have no doubt, be able to explain the phenomena. If, after reading these, you are still perplexed write again, and we will endeavour to make clear what now appears difficult.*

PATENT LAW REFORM.

The very languid interest felt by the general public in the contemplated reform of the Patent Law is not difficult of explanation. So long as the public get what they want, it does not signify who makes the article or who sells it. This, at least, is probably what they would say if they were compelled to account for their indifference to a discussion which among persons immediately affected is carried on with much warmth and not a little acerbity. The fact is, according to popular estimate of the subject, we should get on just as well, and perhaps even better, without any patent laws at all. They are only tolerable on the grounds of long-established usage, and the practical difficulty of otherwise rewarding those who have done the nation some great service in making a valuable discovery or contriving some new and useful device. From the users' point of view, the claim of an inventor to be compensated adequately for the service he has rendered is the one justification of his obtaining a monopoly in the sale of his invention, that being, it is imagined, the only way in which he could be recompensed for his trouble. To the practical statesman the question presents itself in another form. He wishes not merely to pay the inventor, but to encourage invention, so that the country for whose interests he is specially responsible may have the benefit of the best that all the wit and industry of the nation can produce. He offers incentives and rewards for this kind of mental exercise in the form of a patent—the best means yet devised for inducing individuals to benefit their fellow men by their superior ingenuity.

This, roughly speaking, is how the matter stands between the public and those who represent it on the one hand, and the inventor on the other. It is not a particularly elevated view of man's duties and obligations, but it is supposed to be practical; and, at all events, it is the only view at all likely to prevail for some generations to come. Another view of it might be practicable, one that would secure to the owner what is his own and the reward he is entitled to, and to the user the right of using at a fair price what he is willing to pay for. But, unfortunately, nobody will take the trouble to discuss the Patent Laws in a philosophical spirit, partly for reasons already adverted to, but chiefly because nobody is so interested in them as the patent-mongers themselves, who, of course, are influenced by considerations not exclusively or even largely philosophical. They want the Patent Laws upheld because they can make money by them, and they want the existing laws reformed in order to make more money by them. The cry for reform from that quarter has been loud and long; just now the fashion for reforming everything is at its height, and the voice of the patentee has at length been heard.

We sincerely hope that the Bill now before Parliament will not disappoint the people whom it mainly concerns. It hardly concerns the general public at all, or, what amounts to the same thing, the general public could never be persuaded that it does concern them. The framers of the Bill have probably asked the patentee community what it really wanted, and having satisfied themselves that public interests would not be seriously affected by the proposed change, they have let the reformers have their own way. In some respects the law, or rather its interpretation, stands in need of emendation. Recent litigation has made this point only too manifest. There ought to be no sort of doubt as to what constitutes proprietorship, nor should there exist any technical weapons capable of depriving a man of rights that are undeniably his. Whether the measure now before Parliament will, if it become law, render these ever recurring scandals less frequent is another matter. If the examiners perform their duties efficiently in the initial stages of the patent, the after stages ought to be safe from litigation; but very much depends upon the sort of examiners chosen, and, in the opinion of some competent judges, their duties will very soon become either merely perfunctory, or else wholly vexatious.

Experience alone will decide the point just referred to; but in respect to the initial fees we can predict at once

Digitized by Google

what the effect of reducing them will be. The number of patents will be immensely augmented. Some people are pleased to call this a stimulus to invention; we should prefer to call it a subsidy to patent agents. These worthy and painstaking go-betweens are as indispensable to the inventor as solicitors are to the litigant; but it is far from obvious that a large accession to their numbers will be an unmixed gain to the inventor, much less to the public. Inventors will no doubt also greatly multiply. Every petty aid to convenience will be dubbed an invention, as is the case already in America, and a vastly increased number of obscure persons will be anxious to purchase publicity at the small cost of a guinea. The sum total of inventiveness may not thereby be increased; on the contrary, it may even be diminished. But the figures will look big, and the agitators' mouths will be stopped. This is something, though not very much.

For our own part, we are inclined to think that if the securing of a patent is to be made so very easy and so very cheap, it might as well be made still easier and cheaper. Easier certainly it might be made. The fee is but a small fraction of the actual expense. There is the journey to London, which in a general way is desirable though not indispensable. Why not issue the provisional protection everywhere in the shape of a guinea stamp? Officially cancelled and dated on the spot, a document with such a stamp affixed would determine the question of date beyond all dispute, and if posted to the central office within so many hours, its registration and complete validity would be settled—so far, indeed, as the document is concerned. As to its validity as a *bonâ fide* patent, that would depend upon whether it were challenged. The probabilities of its being so challenged will increase with the number of patents issued—a very lively prospect for the lawyers, if not for the patentees and the public at large.

CORRESPONDENCE.

ELECTRICAL MACHINES AND THE TRANSMISSION OF POWER TO A DISTANCE.

(Translation.)

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The note addressed to the Academy of Sciences by M. Hospitalier on the influence exercised by the mode of connecting up dynamo-electric machines in the recent experiments on the transmission of power to a distance, reduces the result that can be attained in transmitting by means of two identical or similar machines to its just proportions. The importance of the question justifies the special mention of M. Hospitalier's communication made in *The Electrician* of March 24. As a sequel to this note I should like to record certain points which result from researches and experiments that I have recently made. You will, perhaps, find that my notes are worthy of attention; and, if so, I beg you will be good enough to publish this letter in your paper.

The complete solution of the problem of the transmission of power by means of electricity does not seem to me to be possible *under actual working conditions*; that is to say, effective work cannot be transmitted by this means with economic and favourable results so long as identical or similar machines are used as generator and receiver.

Most likely it will be necessary to design two very distinct classes of machines—one to be used as generators solely, the others principally as receivers (or motors). When it is required to transmit power to a distance, it will be necessary for the receiver to be of large dimensions as compared with the generator, and possibly it will be found markedly advantageous to build the generators without cores (*sans noyeaux*) and the receivers without wire! This latter arrangement would allow of the reduction of the counter electromotive force, which is at present produced by the second machine. Considerable progress would evidently be made by the suppression or diminution of this counter effect, which results from the fact that the two machines throw into circuit two contrary currents, which nullify each other. But could we hope to realise such a result?

It would be premature to state that this result could be practically and completely attained; but we believe that the solution of the problem of transmitting power by means of electricity for every day uses must be looked for in a modification of the machines to suit the circumstances. This opinion is based on the most striking of the mechanical analogies of electricity. For instance, the phenomena attending the electrical transmission of power are absolutely similar to those observed when two centrifugal ventilating fans are in action, the one being actuated by some motor, and the other receiving its motion from the air emitted by the first, the two being connected by a conducting pipe along which the air is transmitted. The inherent weakness of such a system is seen at once. The fans acting by the centrifugal force developed, and emptying themselves into the same pipe, a large portion of the energy of the motive current of air is uselessly expended in overcoming the inverse current generated by the receiving fan.

Now, the same effects take place in a circuit with two similar dynamo machines. These tend to throw into it contrary currents, having a nullifying effect on each other, and consequently the resultant power is merely the difference between these two actions.

In the pneumatic system we can partly remedy this loss by absorption of a part of the power generated. For, by erecting a fan with a close fitting case, it is always possible to transform the dynamic potential of any sector into static potential. This transformation is necessarily effected by detention. The current of air which is carried from the centre towards the circumference is inflected, and takes an opposite direction. Thus, when any obstacle compels the dynamic centifrugal action to alter its potential this change in the equilibrium of bodies of air in movement must necessarily produce a dynamical reaction. It is sufficient, therefore, so to arrange matters that the motive air current emitted by the first fan shall arrive at the paddles of the second at the exact moment when the transformation of the dynamical action is taking place there. Now, the pressure in the pipe will not meet with counter pressures to partly neutralise it, and its action can be more effectively utilised. To obtain this result, it is only necessary to increase the diameter of the second fan as compared with the first, and to furnish the receiver with a second way of escape for the centrifugal current generated by it. In this way the counter pressure in the sector which is about to receive the motive current will be lowered, and the effective power obtained will be increased.

The analogy between the electrical phenomena developed in a system for transmitting power to a distance by means of electricity, and those which are developed in a pneumatic system, comprising two fans and a pipe to connect them, is so complete that we believe that electrical machines must be modified in an analogous way to the fans if we are to have a satisfactory return from electricity.

Evidently the two dynamos should not be similar. The receiving machine might be usefully furnished with shunt circuits or condensers properly placed, so as to prevent the generation of counter electromotive force in the circuit which connected the two machines.

We condense steam when it has given up its useful work; and are not our most powerful engines worked on this system? The question awaits solution, and I think I have done enough in calling the attention of those interested in the matter to the direction in which researches should be prosecuted.—Yours, &c.,

(Signed) A. BANDSEPT, N.F.

Chaussée de Wavre 15, Bruxelles.

TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can any of your readers furnish statistics as to the various methods and approximate proportions of each of the arrangements used in this country for giving the call signals in connection with telephony? To me the ordinary electric bell and battery with push (used in combination with a switch) seems to be by far the most general arrangement; but surely this is a very expensive and troublesome plan as compared with the magneto-electric generators introduced some time since, and which I may say are universally used in America. These do not depend upon any battery (chemical) for their action, nor has the bell any contact points to get out of order, and from what I have seen of them I think they will keep in order better, give less trouble, and consequently cost less to maintain than the electro-magnetic or "battery" bells. Perhaps there are objections to the introduction of these magneto generators and bells in this country, which objections do not exist in America; if so, I should like to have them pointed out, as it seems so strange that inferior methods should remain in vogue when better are at hand.

These magneto machines are (like the "battery" bells) made up in a combination form, with a switch to operate the telephone and microphone circuits, and, like other things, exist in many forms, some of which are considered better than others. Doubtless a few of your readers are acquainted with and have had experience with various makes of instruments. If so, could they be induced to report their experience as to what they consider the best of these arrangements, and give a comparison between home and American-made apparatus? I do not refer so much to work-bench tests, such as resistances of armatures and bell coils, lifting power of magnets, &c., as I do to the experience noted from the actual running and lasting qualities of the bells. At present there does not seem to be any necessity for powerful generators in this country, *i.e.*, if a magneto will ring well through 100 miles of ordinary line, say 2,500^{m}, it is ample for present and all probable future requirements.—Yours, &c.,

U. Q.

REIS'S TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have just received yours of the 6th. I am sorry I cannot give you any information other than that published in the *Journal of Telegraph Engineers*. I have had very little practical experience with it since I first brought it over beyond making about eight or ten of them. I never attempted articulation, but I easily got a distinction of notes in singing.—Yours, &c.,

W. LADD.

Claremont Villa, Rectory-road, Beckenham,
April 14, 1883.

[Thinking that Mr. Ladd might be able to contribute still further to the history of Reis's telephone, we asked if he could favour us with any other information on the subject. The above is the reply we received from him.—ED. *E.*]

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: From *The Electrician's* account of the testing of the old and new lightning conductors on the General Assembly Hall, Edinburgh, the question arises what should be considered a safe margin to allow when testing a conductor, whether 10, 20, or even 30 ohms? I recently tested one newly erected, and found it to give $\frac{1}{20}$th ohm for metallic circuit, but 95 when to earth. How is that for good?—Yours, &c.,

GOOD EARTH.

HOW IT CAN BE DONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There is one great convenience about the house-to-house supply which has been overlooked. If earth is not used as the return, nothing is easier than to make arrangements with a suitable friend at another part of the circuit to put one side of our respective low resistance lamps or motors to earth, *viâ* water pipe, instead of to the wire in which the meter happens to be, thus saving much wear and tear of the said meters.—Yours, &c.,

JER. DIDDLER.

CONNECTING CONDUCTORS.

The address of the writer of the letter which appeared under this head in our last issue, p. 519, was accidentally omitted. It should have been W. Bridges Adams, Manager, Electric Lighting Supply and Fitting Company, 28, York-street, Westminster, S.W.

THE INSTITUTION OF CIVIL ENGINEERS.

The fourth of the series of six lectures on the Applications of Electricity was delivered on Thursday evening, the 5th of April, by Dr. John Hopkinson, F.R.S., M. Inst. C.E. The subject was "Some Points in Electric Lighting." The following is an abstract of the lecture:—

The science of lighting by electricity was divided by the lecturer into two principal parts—the methods of production of electric currents, and of conversion of the energy of those currents into heat at such a temperature as to be given off in radiations to which the eye was sensible. The laws known to connect together those phenomena called electrical were essentially mechanical in form, closely correlated with mechanical laws, and might be most aptly illustrated by mechanical analogues. For example, the terms "potential," "current," and "resistance," had close analogues respectively in "head," "rate of flow," and "co-efficient of friction" in the hydraulic transmission of power. Exactly as in hydraulics head multiplied by velocity of flow was power measured in foot-pounds per second or in horse-power, so potential multiplied by current was power and was measurable in the same units. Again, just as water flowing in a pipe had inertia and required an expenditure of work to set it in motion, and was capable of producing disruptive effects if that motion were too suddenly arrested, so a current of electricity in a wire had inertia; to set it moving electromotive force must work for a finite time, and if arrested suddenly by breaking the circuit the electricity forced its way across the interval as a spark. Corresponding to mass and moments of inertia in mechanics there existed in electricity co-efficients of self-induction. There was, however, this difference between the inertia of water in a pipe and the inertia of an electric current—the inertia of the water was confined to the water, whereas the inertia of the electric current resided in the surrounding medium. Hence arose the phenomena of induction of currents upon currents, and of magnets upon moving conductors—phenomena which had no immediate analogues in hydraulics.

The laws of induction were then illustrated by means of a mechanical model devised by the late Professor Clerk Maxwell.

In the widest sense, the dynamo-electric machine might be defined as an apparatus for converting mechanical energy into the energy of an electrostatic charge, or mechanical power into its equivalent electric current through a conductor. Under this definition would be included the electrophorus and all frictional machines; but the term was used in a more restricted sense, for those machines which produced electric currents by the motion of conductors in a magnetic field, or by the motion of a magnetic field in the neighbourhood of a conductor. The laws on which the action of such machines was based had been the subject of a series of discoveries. Oersted discovered that an electric current in a conductor exerted force upon a magnet; Ampère that two conductors conveying currents generally exerted a mechanical force upon each other; Faraday discovered—what Helmholtz and Thomson subsequently proved to be the necessary consequence of the mechanical reactions between conductors conveying currents and magnets—namely, that if a closed conductor moved in a magnetic field, there would be a current induced in that conductor in one direction, if the number of lines of magnetic force passed through the conductor was increased by the movement, in the other direction if diminished. Now all dynamo-electric machines were based upon Faraday's discovery. Not only so; but however elaborate it might be desired to make the analysis of the action of a dynamo-machine, Faraday's way of presenting the phenomena of electro-magnetism to the mind was in general the best point of departure. The dynamo-machine, then, essentially consisted of a conductor made

Digitized by Google

to move in a magnetic field. This conductor, with the external circuit, formed a closed circuit in which electric currents were induced as the number of lines of magnetic force passing through the closed circuit varied. Since, then, if the current in a closed circuit was in one direction when the number of lines of force was increasing, and in the opposite direction when they were diminishing, it was clear that the current in each part of such circuit which passed through the magnetic field must be alternating in direction, unless indeed the circuit was such that it was continually cutting more and more lines of force, always in the same direction. Since the current in the wire of the machine was alternating, so also must be the current outside the machine, unless something in the nature of a commutator was employed to reverse the connections of the internal wires in which the current was induced, and of the external circuit. There were, then, broadly two classes of dynamo-electric machines; the simplest, the alternating-current machine, where no commutator was used; and the continuous-current machine, in which a commutator was used to change the connection with the external circuit just at the moment when the direction of the current would change. The theory of the alternate-current machine was then explained, and it was proved that two independently driven alternate-current machines could not be worked in series, but that they might be worked in parallel circuit, and hence were quite suitable for distribution of electricity for lighting without the necessity of providing a separate circuit for each machine.

It was easy to see that, by introducing a commutator revolving with the armature in an alternate-current machine, and so arranged as to reverse the connection between the armature and the external circuit just at the time when the current would reverse, it was possible to obtain a current constant always in direction; but such a current would be far from constant in intensity, and would certainly not accomplish all the results obtained in modern continuous-current machines. This irregularity might, however, be reduced to any extent by multiplying the wires of the armature, giving each its own connection to the outer circuit, and so placing them that the electromotive force attained a maximum successively in the several coils. A practically uniform electric current was first commercially produced with the ring armature of Pacinotti, as perfected by Gramme. A dynamo-machine was not a perfect instrument for converting mechanical energy into the energy of electric current. Certain losses inevitably occurred. There was the loss due to friction of bearings, and of the collecting-brushes upon the commutator; there was also the loss due to the production of electric currents in the iron of the machine. When these were accounted for, there remained the actual electrical effect of the machine in the conducting wire; but all of this was not available for external work. The current had to circulate through the armature, which inevitably had electrical resistance; electrical energy must, therefore, be converted into heat in the armature of the machine. Energy must also be expended in the wire of the electro-magnet which produced the field, as the resistance of this also could not be reduced beyond a certain limit. The loss by the resistance of the wires of the armature and of the magnets greatly depended on the dimensions of the machine. To know the properties of any machine thoroughly, it was not enough to know its efficiency and the amount of work it was capable of doing; it was necessary to know what it would do under all circumstances of varying resistance or varying electromotive force; and, under any given conditions, what would be the electromotive force of the armature? Now this electromotive force depended on the intensity of the magnetic field, and the intensity of the magnetic field depended on the current passing round the electro-magnet and the current in the armature. The current then in the machine was the proper independent variable in terms of which to express the electromotive force. The simplest case was that of the series-dynamo, in which the current in the electro-magnet and in the armature was the same, for then there was only one independent variable. The relation between electromotive force and current might be most conveniently expressed by a curve.

When, four years ago, the lecturer first used such a curve (since named by Deprez the "characteristic curve") for the purpose of expressing the results of his experiments on the Siemens dynamo-machine, he pointed out that it was capable of solving almost any problem relating to a particular machine, and that it was also capable of giving good indications of the results of changes in the winding of the magnets, or of the armatures of such machines. The use of the characteristic curve was illustrated with reference to charging accumulators and Jacobi's law of electric transmission of power.

When the dynamo-machine was not a series-dynamo, but the current in the armature and in the electro-magnet, though possibly dependent upon each other, were not necessarily equal, the problem was not so simple. In that case there were two variables, the current in the electro-magnet and the current in the armature; and the proper representation of the properties of the machine would be by a characteristic surface, of which a model was exhibited. By the aid of such a surface any problem relating to a dynamo-machine could be dealt with, no matter how its electro-magnets and its armature were connected together. Of course, in actual practice the model of the surface would not be used, but the projections of its sections.

The properties of a machine depended much upon its dimensions. Suppose two machines alike in every particular, excepting that the one had all its linear dimensions double that of the other. The electrical resistances in the larger machine would be one-half those of the smaller. The current required to produce a given intensity of magnetic field would be twice as great in the larger machine as in the smaller. The comparative characteristic curves of the two machines, when driven at the same speed, were shown in a diagram. The two curves were one the projection of the other, having corresponding points with abscisses in the ratio of one to two, and the ordinates in the ratio of one to four. At first sight it would seem that the work done by the larger machine should be thirty-two times as much as that which would be done by the smaller. Practically, however, no such result could possibly be attained, for many reasons. First, the iron of the magnets became saturated, and consequently, instead of eight times the electromotive force, there would only be four times the electromotive force. Secondly, the current which the armature could carry was limited by the rate at which the heat generated in the armature could escape. Again, the larger machine could not run at so great an angular velocity as the smaller one. And lastly, since in the larger machine the current in the armature was greater in proportion to the saturated magnetic field than in the smaller one, the displacement of the point of contact of the brushes with the commutator would be greater. Shortly, the capacity of similar dynamo-machines was pretty nearly proportionate to their weight, that was to the cube of their linear dimensions. The work wasted in producing the magnetic field was directly as the linear dimensions; and the work wasted in heating the wires of the armature was as the square of the linear dimensions.

A consideration of the properties of similar machines had another important practical use. Mr. Froude was able to control the design of ironclad ships by experiments upon models made in paraffin wax. It was a much easier thing to predict what the performance of a large dynamo machine would be from laboratory experiments made upon a model of a very small fraction of its dimensions. As a proof of the practical utility of such methods, the lecturer stated that by laboratory experiments he had succeeded in greatly increasing the capacity of the Edison machines, without increasing their cost, and with a small increase of their percentage of efficiency, remarkably high as that efficiency already was.

The electric properties of the electric arc were experimentally illustrated; in particular it was shown that the difference of potential between the carbons was nearly independent of the current.

When a current of electricity passed through a continuous conductor, it encountered resistance, and heat was generated, as shown by Joule, at a rate represented by the resistance multiplied by the square of the current. If the current was sufficiently great, heat would be generated at such a rate that the conductor would become incandescent and radiate light. Attempts had been made to use platinum and platinum iridium as the incandescent conductor. But these bodies were too expensive for general use, and besides that, refractory though they were, they were not refractory enough to stand the high temperature required for incandescent lighting, which should be economical of power. Commercial success was not realised until very thin and very uniform threads or filaments of carbon were produced and enclosed in reservoirs of glass, from which the air was exhausted to the utmost possible limit. Such were the lamps made by Mr. Edison, with which the Institution was temporarily lighted. The electrical properties of such a lamp were examined, and in particular it was shown that its efficiency increased and its resistance diminished with increase of current.

The building was lighted by about 230 lamps, each giving sixteen candles light, produced each by seventy-five watts of power developed in the lamp. To produce the same sixteen candles light in ordinary good flat-flame gas-burners, would require between seven and eight cubic feet of gas per hour, contributing heat to the atmoshere at the rate of 3,400,000 ft.-lbs. per hour, equivalent to 1,250 watts, or nearly seventeen times as much heat as the incandescence lamp of equal power.

At the present time, lighting by electricity in London must cost something more than lighting by gas. What were the prospects of reduction of this cost? Beginning with the engine and boiler, the electrician had no right to look forward to any marked and exceptional advance in their economy. Next came

Digitized by Google

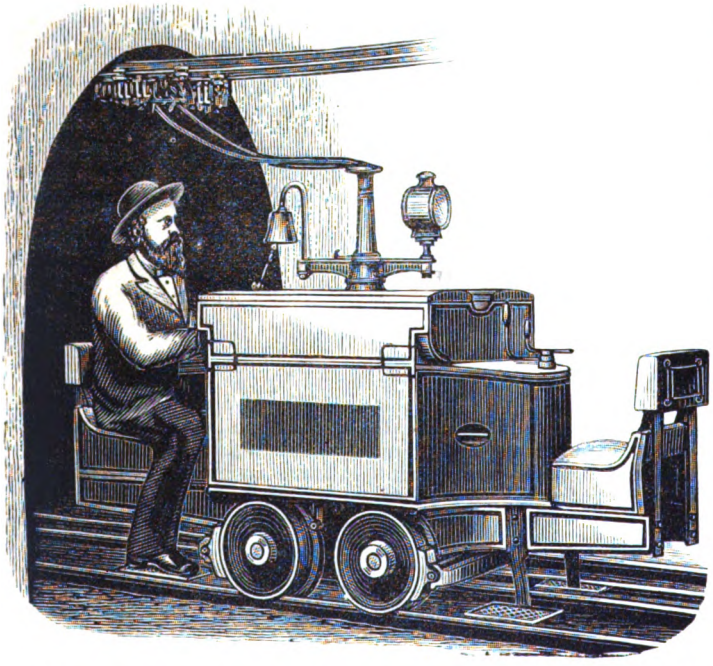
the dynamo. The best of these were so good that there was little room for economy in the conversion of mechanical into electrical energy; but the prime cost of the dynamo-machine was sure to be greatly reduced. Hope of considerably increased economy must be mainly based upon probable improvements in the incandescence lamp, and to this the greateast attention ought to be directed. It had been shown that marked economy of power could be obtained by working the lamps at high pressure, but then they soon broke down. In ordinary practice, from 140 to 200 candles were obtained from 1 horse-power developed in the lamps, but for a short time he had seen over 1,000 candles per horse-power from incandescence lamps. The problem, then, was so to improve the lamp in details, that it would last a reasonable time when pressed to that degree of efficiency. There was no theoretical bar to such improvements, and it must be remembered that incandescence lamps had only been articles of commerce for about three years, and already much had been done. If such an improvement were realised, it would mean that it would be possible to get five times as much light for a sovereign as could be done now. At present electric lighting would succeed commercially where other considerations than cost had weight. Improvements in the lamps were certain, and there was a probability that these improvements might go so far as to reduce the cost to one-fifth of what it now was. He left the meeting to judge whether or not it was probable, nay, almost certain, that lighting by electricity was to be the lighting of the future.

I. THE TRANSMISSION OF POWER BY ELECTRICITY.*
II. THE PORTRUSH ELECTRICAL RAILWAY.

BY ALEXANDER SIEMENS AND EDWARD HOPKINSON, D.SC.

(CONCLUDED FROM PAGE 524.)

Now let us put these considerations in a mathematical form. The first problem is :—Given a main with a constant E.M.F. de-



View of engine employed at the mines at Zankerode, in Saxony, an illustration of which was shown at the meeting by Mr. Siemens (*see* p. 523 of our last issue). The dynamo is placed with its axis lengthwise on the car, and works one pair of driving wheels by means of bevel gear. The current is conveyed along the roof of the workings by means of an inverted tee iron rail, on which a contact carriage freely slides, and connects with the engine by a flexible cable carried down the tube. The return current is taken by a similar cable and carriage to a second conductor, fixed by the side of the first.

noted by E, to construct a dynamo machine, drawing its current from the main, to work with a given load, L, and at a given number of revolutions, n, per minute. Let us make use of the characteristic curves, used by Dr. J. Hopkinson, Dr. Frölich, M. Marcel Deprez, and others.

Take Ox, Oy (Fig. 1) as axes of co-ordinates, along Oy, cut off

* Paper read before the Society of Arts on Wednesday, April 11, 1883.

O M, representing the E.M.F. of the main in volts. Now makers of each type of dynamo machine know approximately the percentage of energy their machines absorb in producing the necessary magnetic field. Take a point, N, in O M, such that the ratio $\frac{O\,N}{O\,M}$ is equal to this percentage. Again, it is known that a dynamo is not an absolutely perfect machine, but that a certain amount of energy is wasted in the friction of the bearings, and of the brushes against the commutator, and also in induced currents in the core of the armature. Take O R, such that $\frac{O\,R}{O\,N}$ represents the efficiency of the machine. This, in the case of the Siemens

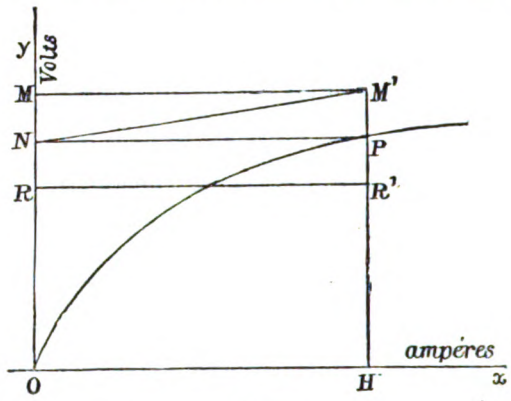


Fig. 1.

machine, is at least 90 per cent. From Ox cut off O H, such that the rectangle O H R′ R represents the power required from the motor expressed in watts. Then O H is the current passing through the motor, measured in amperes, and H P is the inverse E.M.F. The proper motor, therefore, is that dynamo which, when running at the given number of revolutions n per minute, has a characteristic curve passing through the point P. The total efficiency is evidently the ratio of the rectangle O H R′ R to the rectangles O H M′ M, which is equal to $\frac{H\,R'}{H\,M'}$; the electrical efficiency is $\frac{H\,P}{H\,M'} = \frac{E'}{E}$, the ratio of the inverse E.M.F. of the motor to the E.M.F. of the main. The energy spent in magnetisation is measured by P N M M′, and the tangent of the angle P N M′ represents the resistance of the armature and magnets.

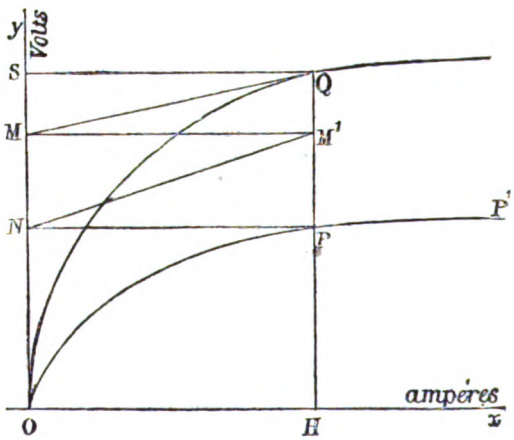

Fig. 2.

The second problem is :—Given a motor requiring a certain current and E.M.F. for the work it has to do, to construct a suitable generator, the distance between the machines being represented by an electrical resistance R measured in ohms. Let O P P′ (Fig. 2) be the characteristic curve of the motor, when running at the required speed; P H the E.M.F. in volts, and Q H the current in amperes. Let R′ be the sum of the resistances of the motors, and R conductor. Draw P N perpendicular to Oy, and make the angle P N M′, having its tangent equal to R′; then M′ H represents the difference of potential between the terminals of the generator. Produce H M′ to Q, so that $\frac{Q\,M'}{Q\,H}$ is the ratio of the energy expended in producing the magnetic field to the total energy of the machine; then the

Digitized by Google

generator is that dynamo which, when running at its proper speed, has a characteristic curve passing through the point Q.

The electrical efficiency of the combination is the ratio $\frac{PH}{QH'}$, *i.e.*, the ratio of the E.M.F. of the motor to the E.M.F. of the generator, which, if the machines are similar, is equal to the ratio of their speeds. The energy converted into heat in the wires of the machine, and in the conductor, is NPQS; and the total efficiency of the combination is the ratio of the electromotive forces, multiplied by the product of the efficiencies of the two machines, considered separately. The conductor connecting the two machines has been considered to be perfectly insulated. Of course, this is not practically attained, but I will not now consider the point particularly, as it is has very recently been discussed from an analytical point of view by Dr. O. J. Lodge.

The diagrams might be used for proving many other points of interest in connection with the theory of transmission of power, especially Jacobi's law of maximum effect; but I think it will probably be of more advantage to leave the rest of the time at our disposal to Dr. Edward Hopkinson, to describe the Portrush Railway, the electrical part of the work of which he has had in charge, under the direction of Dr. Siemens, particularly as it will illustrate how these principles have been carried out in practice, and the results obtained therefrom.

II. The Portrush Railway.

In the summer of 1881, Mr. W. A. Traill, late of H.M. Geological Survey, suggested to Dr. Siemens that the line between Portrush and Bushmills, for which parliamentary powers had been obtained, would be suitable in many respects for electrical working, especially as there was abundant water-power available in the neighbourhood. Dr. Siemens at once joined in the undertaking, which has been carried out under his direction. The line extends from Portrush, the terminus of the Belfast and Northern Counties Railway, to Bushmills in the Bush Valley, a distance of six miles. For about half a mile the line passes down the principal street of Portrush, and has an extension along the Northern Counties Railway to the harbour. For the rest of the distance, the rails are laid on the seaside of the county road, and the head of the rails being level with the ground, a footpath is formed the whole distance, separated from the road by a kerb-stone. The line is single, and has a gauge of three feet, the standard of the existing narrow gauge lines in Ulster. The gradients are exceedingly heavy, as will be seen from the diagram, being in parts as steep as 1 in 35. The curves are also in many cases very sharp, having necessarily to follow the existing road. There are five passing places in addition to the sidings at the termini and at the carriage depôt. At the Bushmills end the line is laid for about 200 yards along the street, and ends in the market-place of the town. It is intended to connect it with an electrical railway from Dervock, for which parliamentary powers have already been obtained, thus completing the connection with the narrow gauge system from Ballymena to Larne and Cushendall. About 1,500 yards from the end of the line there is a waterfall on the River Bush, with an available head of 24ft., and an abundant supply of water at all seasons of the year. Turbines are now being erected, and the necessary works executed for employing the fall for working the generating dynamo machines, and the current will be conveyed by means of an underground cable to the end of the line. Of the application of the water-power it is unnecessary to speak further, as the works are not yet completed. For the present the line is worked by a small steam engine placed at the carriage depôt at the Portrush end. The whole of the constructive works have been designed and carried out by Mr. Traill, assisted by Mr. E. B. Price.

The system employed may be described as that of the separate conductor. A rail of tee-iron, weighing 19lbs. to the yard, is carried on wooden posts, boiled in pitch, and placed 10 feet apart, at a distance of 22 inches from the inside rail and 17 inches above the ground. This rail comes close up against the fence on the side of the road, thus forming an additional protection. The conductor is connected by an underground cable, to a single shunt-wound dynamo machine, placed in the engine shed, and worked by a small agricultural steam-engine of about 25 indicated horse-power. The current is conveyed from the conductor by means of two springs, made of steel, rigidly held by two steel bars placed one at each end of the car, and projecting about six inches from the side. Since the conducting rail is iron, while the brushes are steel, the wear of the latter is exceedingly small. In dry weather they require the rail to be slightly lubricated; in wet weather the water on the surface of the iron provides all the lubrication required. The double brushes, placed at the extremities of the car, enable it to bridge over the numerous gaps, which necessarily interrupt the conductor to allow cart ways into the fields and commons adjoining the shore. On the diagram the car is shown passing one of these gaps; the front brush has broken contact, but since the back brush is still touching the rail the current has not been broken. Before the back brush leaves the conductor the front brush will have again risen upon it, so that the current is never interrupted. There are two or three gaps too broad to be bridged in this way. In these cases the driver will break the current before reaching the gap, the momentum of the car carrying it the 10 or 12 yards it must travel without power.

The current is conveyed under the gaps by means of an insulated copper cable carried in wrought-iron pipes placed at a depth of 18 inches. At the passing places, which are situated on inclines, the conductor takes the inside, and the car ascending the hill also runs on the inside, while the car descending the hill proceeds by gravity on the outside lines.

From the brushes the current is taken to a commutator worked by a lever, which switches resistance-frames placed under the car, in or out, as may be desired. The same lever alters the position of the brushes on the commutator of the dynamo machine, reversing the direction of rotation, in the manner shown by the electrical hoist. The current is not, as it were, turned full on suddenly, but passes through the resistances, which are afterwards cut out in part or altogether, according as the driver desires to run at part speed or full speed.

From the dynamo, the current is conveyed through the axle-boxes to the axles, thence to the tyres of the wheels, and finally back by the rails, which are uninsulated, to the generating machine. The conductor is laid in lengths of about 21ft., the lengths being connected by fish plates and also by a double copper loop securely soldered to the iron. It is also necessary that the rails of the permanent way should be connected in a similar manner, as the ordinary fish-plates give a very uncertain electrical contact, and the earth for large currents is altogether untrustworthy as a conductor, though no doubt materially reducing the total resistance of the circuit.

The dynamo is placed in the centre of the car, beneath the floor, and through intermediate spur gear drives by a steel chain on to one axle only. The reversing levers, and also the levers working the mechanical brakes, are connected to both ends of the car, so that the driver can always stand at the front and have uninterrupted view of the rails, which is, of course, essential in the case of a line laid by the side of the public road.

The cars are first and third class, some open and some covered, and are constructed to hold twenty people, exclusive of the driver. At present, only one is fitted with a dynamo, but four more machines are now being constructed by Messrs. Siemens Brothers, so that before the beginning of the heavy summer traffic five cars will be ready; and since two of these will be fitted with machines capable of drawing a second car, there will be an available rolling stock of seven cars. It is not intended at present to work electrically the portion of the line in the town at Portrush, though this will probably be done hereafter; and a portion, at least, of the mineral traffic will be left for the two steam tramway engines, which were obtained for the temporary working of the line pending the completion of the electrical arrangements.

Let us now put in a form suitable for calculation, the principles which Mr. Siemens has illustrated in a graphic form more convenient for the purposes of explanation, and then show how these principles have been applied in the present case.

Let L be the couple, measured in foot-pounds, which the dynamo must exert in order to drive the car, and w the necessary angular velocity. Taking the tare of the car as 50 cwt., including the weight of the machinery it carries, and a load of twenty people as 30 cwt., we have a gross weight of 4 tons. Assume that the maximum required is that the car should carry this load at a speed of seven miles an hour, on an incline of 1 in 40. The resistance due to gravity may be taken as 56lb. per ton, and the frictional resistance, and that due to other causes, say 14lb. per ton, giving a total resistance of 280lb., at a radius of 14in. The angular velocity of the axle corresponding to a speed of seven miles an hour is 84 revolutions per minute. Hence L = 327 foot-pounds, and $w = \frac{2\pi \times 84}{60}$.

If the dynamo be wound directly on the axle, it must be designed to exert the couple L, corresponding to the maximum load, when revolving at an angular velocity w, the difference of potential between the terminals being the available E.M.F. of the conductor, and the current the maximum the armature will safely stand. This will be the case in the Charing-cross Electrical Railway. But when the dynamo is connected by intermediate gear to the driving wheels only the product of L and w remains constant, and the two factors may be varied. In the present case L is diminished in the ratio of 7 to 1, and w conse-

Digitized by Google

quently increased in the same ratio. Hence the dynamo, with its maximum load, must revolve at 588 revolutions per minute, and exert a couple of 47 foot-pounds. Let E be the potential of the conductor from which the current is drawn, measured in volts, C the current in amperes, and E_1 the E.M.F. of the dynamo. Then E_1 is proportional to the product of the angular velocity, and a certain function of the current. For a velocity, ω, let this function be denoted by $f(C)$. If the characteristic of the dynamo can be drawn, then $f(C)$ is known.

We have then

$$E_1 = \frac{w}{\Omega} f(C). \quad . \quad . \quad . \quad . \quad . \quad . \quad (1.)$$

If R be the resistance in circuit, by Ohm's law,

$$C = \frac{E - E_1}{R} = \frac{E - \frac{w}{\Omega} f(C)}{R}$$

And, therefore,

$$w = \frac{\Omega (E - C R)}{f(C)}. \quad . \quad . \quad . \quad . \quad . \quad (2.)$$

Let a be the efficiency with which the motor transforms electrical into mechanical energy, then—

$$\text{Power required} = L w = a E_1 C, = a C \frac{w}{\Omega} f(C).$$

Dividing by w,

$$L = \frac{a C f(C)}{\Omega}. \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

It must be noted that L is here measured in electrical measure, or adopting the unit given by Dr. Siemens in the British Association address in joules. One joule equals approximately ·74 foot-pounds. Equation (3) gives at once an analytical proof of the second principle stated above, and that for a given motor the current depends upon the couple, and upon it alone. Equation (2) shows that with a given load the speed depends upon E, the electromotive force of the main, and R the resistance in circuit. It shows also the effect of putting into the circuit the resistance frames placed beneath the car. If R be increased until C R is equal to E, then w vanishes, and the car remains at rest. If R be still further increased, Ohm's law applies, and the current diminishes. Hence, suitable resistances are—first, a high resistance for diminishing the current, and, consequently, the sparking at making and breaking of the circuit; and, secondly, one or more low resistances for varying the speed of the car. If the form of $f(C)$ be known, as is the case with a Siemens machine, Equations (2) and (3) can be completely solved for w and C, giving the current and speed in terms of L E and R. The expressions so obtained are not without interest, and agree with the results of experiment.

It may be observed that an arc light presents the converse case to a motor. The E.M.F. of the arc is approximately constant, whatever the intensity of the current passing between the carbons; and the current depends entirely on the resistance in circuit. Hence the instability of an arc produced by machines of low internal resistance, unless compensated by considerable resistance in the leads.

The following experiment shows in a striking form the principles just considered. An Edison lamp is placed in parallel circuit with a small dynamo machine used as a motor. The Prony brake on the pulley of the dynamo is quite slack, allowing it to revolve freely. Now let the lamp and dynamo be coupled to the generator running at full speed. First, the lamp glows, in a moment it again becomes dark, then, as the dynamo gets up speed, glows again. If the brake be screwed up tight the lamp once more becomes dark. The explanation is simple. Owing to the co-efficient of self-induction of the dynamo machine being considerable, it takes a finite time for the current to obtain an appreciable intensity, but the lamp having no self-induction, the current at once passes through it, and causes it to glow. Secondly, the electrical inertia of the dynamo being overcome, it must draw a large current to produce the kinetic energy of rotation, *i.e.*, to overcome its mechanical inertia; the lamp is therefore practically short-circuited, and ceases to flow. When once the rotation has been established, the current through the dynamo becomes very small, having no work to do except to overcome the friction of the bearings, hence the lamp again glows. Finally, by screwing up the brake, the current through the dynamo is increased, and the lamp again short-circuited.

It has often been pointed out that reversal of the motor on the car would be a most effective brake. This is certainly true; but, at the same time, it is a brake that should not be used except in cases of emergency. For this reason, the dynamo revolving at a high speed the momentum of the current is very considerable; hence, owing to the self-induction of the machine, a sudden reversal will tend to break down the insulation at any weak point of the machine. The action is analogous to the spark produced by a Ruhmkorff coil. This was illustrated at Portrush. When the car was running perhaps fifteen miles an hour the current was suddenly reversed. The car came to a standstill in little more than its own length, but at the expense of breaking down the insulation of one of the wires of the magnet coils. The way out of the difficulty is evidently at the moment of reversal to insert a high resistance to diminish the momentum of the current.

In determining the proper dimensions of a conductor for railway purposes Sir William Thomson's law should properly apply, but on a line where the gradients and traffic are very irregular it is difficult to estimate the average current; and the desirability of having the rail mechanically strong, and of such low resistance that the potential shall not vary very materially throughout its length, becomes more important than the economic considerations involved in Sir William Thomson's law. At Portrush the resistance of a mile, including the return by earth and the ground rails is actually about 0·23 ohm. If calculated from the section of the iron it would be 0·15 ohm, the difference being accounted for by the resistance of the copper loops, and occasional imperfect contacts. The E.M.F. at which the conductor is maintained is about 225 volts, which is well within the limit of perfect safety assigned by Sir William Thomson and Dr. Siemens. At the same time the shock received by touching the iron is sufficient to be unpleasant, and hence is some protection against the conductor being tampered with.

Consider a car requiring a given constant current; evidently the maximum loss due to resistance will occur when the car is at the middle point of the line, and will then be one-fourth of the total resistance of the line, provided the two extremities are maintained by the generators at the same potential. Again, by integration, the mean resistance can be shown to be one-sixth of the resistance of the line. Applying these figures, and assuming four cars are running, requiring 4 horse-power each, the loss due to resistance does not exceed 4 per cent. of the power developed on the cars; or if one car only be running, the loss is less than 1 per cent. But in actual practice at Portrush even these estimates are too high, as the generators are placed at the bottom of the hills, and the middle portion of the line is more or less level, hence the minimum current is required when the resistance is at its maximum value.

The insulation of the conductor has been a matter of considerable difficulty, chiefly on account of the moistness of the climate. An insulation has now, however, been obtained of from 500 to 1,000 ohms per mile, according to the weather, by placing a cap of insulite between the wooden posts and tee-iron (see Fig. 3).

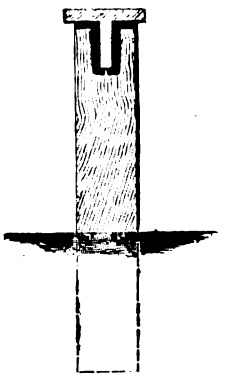

Fig. 3.

Hence the total leakage cannot exceed 2·5 amperes, representing a loss of three-fourths of a horse-power, or under 5 per cent., when four cars are running. But, apart from these figures, we have materials for an actual comparison of the cost of working the line by electricity and steam. The steam tramway engines temporarily employed at Portrush are made by Messrs. Wilkinson, of Wigan, and are generally considered as satisfactory as any of the various tramway engines. They have a pair of vertical cylinders 8in. diameter, and 1ft. stroke, and work at a boiler pressure of 120lb., the total weight of the engine being 7 tons. The electrical car with which the comparison is made has a dynamo weighing 13 cwt., and the tare of the car is 52 cwt. The steam engines are capable of drawing a total load of about 12 tons up the hill, excluding the weight of the engine; the dynamo over 6 tons, excluding its own weight; hence, weight for weight, the dynamo will draw five times as much as the steam engine. Finally, compare the following estimates of cost. From actual

Digitized by Google

experience, the steam engine, taking an average over a week, costs:—

	£	s.	d.
Driver's wages	1	10	0
Cleaner's ditto	0	12	0
Coke, 58½ cwt., at 25s. per ton	3	13	1½
Oil, 1 gallon, at 3s. 1d.	0	3	1
Tallow, 4lb., at 6d.	0	2	0
Waste, 8lb., at 2d.	0	1	4
Depreciation, 15 per cent. on £750	2	3	3
Total	£8	4	9½

The distance run was 312 miles. Also, from actual experience, the electrical car, drawing a second behind it, and hence providing for the same number of passengers, consumed 18lb. of coke per mile run. Hence, calculating the cost in the same way, for a distance run of 312 miles in a week—

	£	s.	d.
Wages of stoker of stationary engine	1	0	0
Coke, 52 cwt., at 25s. per ton	2	15	0
Oil, 1 gallon, at 3s. 1d.	0	3	1
Waste, 4lb., at 2d.	0	0	8
Depreciation on stationary engine, 10 per cent. on £300, 11s. 6d. Depreciation of electrical apparatus, 15 per cent. on £500, £1 8s. 10d.	2	0	4
Total	£5	19	1

A saving of over 25 per cent.

The total mileage run is very small, on account of the light traffic early in the year. Heavier traffic will tell very much in favour of the electric car, as the loss due to leakage will be a much smaller proportion of the total power developed.

It will be observed that the cost of the tramway engines is very much in excess of what is usual on other lines, but this is entirely accounted for by the high price of coke, and the exceedingly difficult nature of the line to work on account of the curves and gradients. These causes send up the cost of electrical working in the same ratio, hence the comparison is valid as between the steam and electricity, but it would be unsafe to compare the cost of either with horse-traction or wire rope traction on other lines. The same fuel was burnt in the stationary steam engine and in the tramway engines, and the same rolling stock used in both cases; but, otherwise, the comparison was made under circumstances in favour of the tramway engine, as the stationary steam engine is by no means economical, consuming at least 5lb. of coke per horse-power hour, and the experiments were made, in the case of the electrical car, over a length of line three miles long, which included the worst hills and curves, and one half of the conductor was not provided with the insulite caps, the leakage consequently being considerably larger than it will be eventually.

Finally, as regards the speed of the electrical car, it is capable of running on the level at the rate of twelve miles per hour, but as the line is technically a tramway, the Board of Trade Regulations do not allow the speed to exceed ten miles an hour.

Taking these data as to cost, and remembering how this will be reduced when the water power is made available, and remembering such considerations as the freedom from smoke and steam, the diminished wear and tear of the permanent way, and the advantage of having each car independent, it may be said that there is a future for electrical railways.

We must not conclude without expressing our best thanks to Messrs. Siemens Bros. for having kindly placed all this apparatus at our disposal to-night, and allowing us to publish the results of experiments made at their works.

ON MICROPHONIC CONTACTS.*

BY SHELFORD BIDWELL, M.A., LL.B.

It is generally admitted that the variation of the electrical resistance of two conductors in contact, under different degrees of pressure, was first observed by M. du Moncel, whose researches on the subject were published in 1856. This principle was applied ten years later by M. Clerac in the construction of rheostats, the resistance of which was varied by the pressure of a piston upon powdered carbon contained in an insulating tube. In July, 1877, Mr. Edison took out a patent for his celebrated telephone transmitter, in which the varying pressure of a tympanum or diaphragm upon a semi-conducting material was used to regulate the strength of an electric current in such a manner as to render it capable of reproducing speech in a suitable receiver.

* A paper read at the meeting of the Society of Telegraph Engineers, April 12, 1883.

On May 9, 1878, a very remarkable paper was read before the Royal Society by Professor Hughes. It was entitled "The Action of Sonorous Vibrations in Varying the Force of an Electric Current," and contained descriptions of a great number of experiments, which showed in effect that apparatus of the very simplest description, consisting merely of loose contacts of any substance which would conduct electricity, could be used, not only for transmitting speech, but for rendering audible in the telephone sounds which to the unassisted ear were quite inappreciable. It is to this latter property that the microphone, with which the name of Professor Hughes will always be associated, owes its title.

Though at the present time the matter is of great practical importance, there is much in the details of the behaviour of microphonic contacts which has not hitherto been fully investigated or satisfactorily explained; and it was for the purpose of throwing some little additional light on the subject, and, if possible, clearing up certain apparent anomalies connected with it, that the experiments described in this paper were undertaken.

Loose contacts are proverbial for the uncertainty of their action, and it was to be expected that the investigation would prove troublesome, and the results obtained by no means uniform. But by multiplying experiments, the element of uncertainty has been to a great extent removed, and several interesting facts, not, I think, previously noticed, seem to be clearly established.

The first requisite was an instrument for accurately measuring and regulating the pressure between the conducting materials. Several devices were tried, and successively abandoned as unsatisfactory. The arrangement which was finally adopted, and which was used for nearly all the experiments, is shown in Fig. 1. The apparatus consists of a little balance. H K is a light steel rod (formed of a fine knitting needle), balanced at C on a knife-edge which is fixed at right angles to it. To one end, K, is attached a split tube of thin copper for holding short rods of the different substances to be tested, which are held so as to press at right angles upon another rod, R, held in a spring clamp. Midway between C and K is hung the scale-pan S, and at H is a sliding counterpoise, which at the beginning of an experiment is so adjusted that a weight of ·01 gramme in the scale-pan will just bring K and R into contact with each other. Electrical connection is made through the wires W_1 and W_2, the former of which is attached to the clamp holding R, and the latter communicates with a mercury cup, into which dips a wire attached to the rod H K at the point C. It is evident that the pressure between K and R will be equal to half the weight in the scale-pan S.

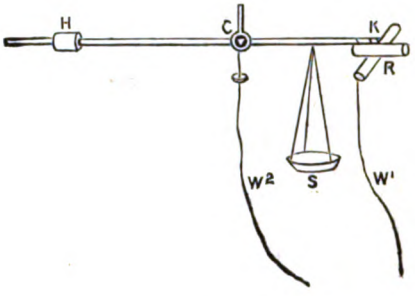

Fig. 1.

The object of the first experiments was to ascertain the effects of various pressures upon the resistance of two carbon rods in the positions shown at K and R, the measurements being made with a Wheatstone bridge in the ordinary manner. The rods selected were electric light pencils of gas carbon, 6 mm. in diameter. In all, seventeen series of observations were thus made, the weights in the scale-pan varying from ·5 gramme to 100 grammes. The mean of three of these, which were performed with the same balance, and under as nearly as possible the same conditions, is given in the following table:—

Table 1.

Relation between the pressure of carbon contacts and their resistance when measured in the ordinary way.

Pressure.	Resistance.	Pressure.	Resistance.
Grammes.	Ohms.	Grammes.	Ohms.
·25	16·10	5	4·23
·5	11·00	7·5	3·53
1	8·43	10	3·06
1·5	6·70	12·5	2·80
2	6·15	15	2·60
2·5	5·90	17·5	2·46
3	5·13	20	2·33
3·5	5·00	25	2·16
4	4·60	50	1·86
4·5	4·33		

In making these measurements the details of the arrangements were from time to time varied. Different proportional coils were used and different numbers of battery cells, and it soon became evident that the resistance of the carbon contact was largely dependent on the electromotive force or the strength of the current used.

Table II. gives the means of two series of observations, and shows the result of using one, two, three, and four cells successively.

10	1·50	1·45	1·40	1·35
25	1·15	1·05	1·05	1·05

It became interesting to ascertain what would be the effect of making still further variations in the strength of the measuring current. A box of resistance coils was, therefore, inserted between the battery (2 Leclanché's) and the bridge arrangement, and, the weight in the pan remaining the same, various resistances were successively unplugged in the box. Table III. gives a few of the measurements with pressures of ·5, 2·5, 7·5, and 25 grammes. This table shows that the resistance of the carbon contacts varies greatly with the strength of the current when the pressure is small, and but very slightly when the pressure is great.

TABLE III.

1,000	9·7	3·1	1·9	1·03

It is clear, therefore, that the diminution of resistance which occurs when the pressure between carbon contacts is increased is not under ordinary circumstances due solely to the increase of pressure; for the diminished resistance which results from the increased pressure causes an increase in the strength of the current, the effect of which is a still further fall in the resistance. Thus, the total diminution of resistance is due only partly to increase of pressure, and partly also to increased strength of current.

An experiment was devised for exhibiting this effect in a conspicuous manner. The arrangement of the apparatus is shown in Fig. 2. a, n, a

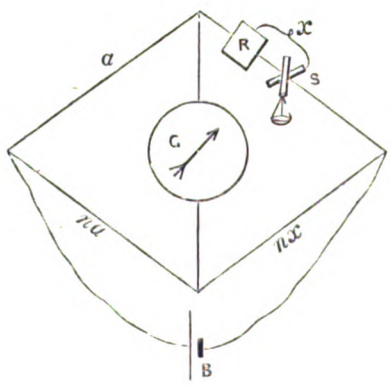

FIG. 2.

$n\,x$, and x are the arms of an ordinary Wheatstone bridge arrangement, B is a battery, and G a reflecting galvanometer. In the arm x is placed the carbon balance S, and in the same arm a box of resistance coils, R; at a is a resistance of 2 ohms, and at n a 1,000 ohms. All the resistance being plugged out of R, the resistance of S, with a weight of 1 gramme in the scale-pan, was found to be 6·4 ohms. Two grammes were then put in the scale-pan, and the resistance fell to 5·1 ohms. In order to ascertain how much of this effect was due to increased strength of current, a resistance was inserted at R sufficient to reduce the current to its original strength—that is, in the present case, sufficient to make the total resistance, S + R, equal to the original resistance of 6·4 ohms. Now, in order to bring up the total resistance to 6·4 ohms, it was found necessary to insert at R, not 1·3 ohm, as might have been expected, but exactly 1 ohm. The resistance of the carbon alone was now (6·4 ohms — 1 ohm =) 5·4 ohms, a weight of 2 grammes being in the scale-pan, but the current the same as when only 1 gramme was in the scale-pan. The further reduction of 0·3 ohm when the measurement was made without the added resistance was due to the increased strength of current consequent upon the increased pressure.

A similar arrangement was then used for determining the resistance of the carbon contacts under gradually increasing pressure, but with a constant current. If E denote the electromotive force of the battery, and B its internal resistance, then the current through the arm containing S will be

$$\frac{n}{n+1} \times \frac{E}{B + \dfrac{n\,(a+x)^2}{(a+x) + n\,(a+x)}}$$

or

$$\frac{n\,E}{(n+1)\,B + n\,(a+x)}$$

From this it is easy to determine what resistances should be inserted in the several branches of the bridge in order to obtain a current through x (and, therfore, through the carbon contacts) of any definite strength. For example, suppose that the electromotive force of our battery is 5 volts, its internal resistance 4·5 ohms, that $a = 10$, $n = 100$, and $n\,a = 1{,}000$, and that we desire a constant current of $\frac{1}{10}$ ampere, then we shall have $\frac{1}{10} = \frac{500}{100\,(x+10) + 101 \times 4{\cdot}5}$. Whence $x = 35{\cdot}5$ nearly

We therefore put a resistance of (35·5 × 100 =)3,550 ohms in the branch $n\,x$, and adjust the resistance in the box R, until the galvanometer indicates a balance. We then know that the resistance of R and S together ($= x$) is 35·5 ohms, and that a current of $\frac{1}{10}$ ampere is passing through R and S. In order to find the resistance of S alone, it is simply necessary to subtract from 35·5 ohms the unplugged resistance in R. It will be understood, therefore, that the resistance in $n\,x$ remains unchanged throughout the experiment, the measurements being made by varying the resistance in R until a balance is obtained.

In Table IV. are given the results obtained with constant currents of ·1 and ·001 ampere, the pressure at the point of contact increasing from ·05 gramme to 25 grammes, all of them representing the mean of several series of measurements. It will be seen that with small pressures the resistance is largely dependent on the strength of the current, but when the pressure is considerable the resistance with weak and strong currents is nearly the same.

TABLE IV.

Effects of pressure upon resistance of carbon contacts with constant currents.

·06	8·9	·2	4·5

A few experiments were made in order to ascertain whether the diminution of resistance under pressure was entirely of a temporary nature, or whether it continued in any degree after the pressure had been removed. It was, of course, necessary to guard against the slightest disturbance of the carbon contacts, and it was found to be exceedingly difficult to remove weights from the scale-pan without risk of causing a material amount of vibration. The arrangement which was finally employed, and which proved to be fairly satisfactory, was as follows:—A 5-gramme weight was attached by a thread to one end of a horizontal lever and placed in the scale-pan, the lever being so fixed that when the other end of it was depressed the weight was raised about a centimetre above the pan; it could thus be taken out and replaced without causing any appreciable oscillation.

A weight of 1 gramme being in the scale-pan, the resistance of the contact was measured with the Wheatstone bridge and one Leclanché cell; the 5-gramme weight was then lowered into the pan, and a measurement made of the diminished resistance. The 5-gramme weight was again gently raised, and the resistance with a single gramme once more measured. In every case it was found to have returned almost exactly to its original value. Table VI. gives six series of measurements thus made.

TABLE VI.

Showing effect upon resistance of increasing and again reducing pressure

·5	20	20	20	19·9	19·5	20·0

The experiment was repeated with a resistance of 300 ohms between the battery and the bridge, that the current might be smaller. The results are contained in Table VII., and are substantially the same as before. It will be noticed, however, that the final resistance is almost invariably slightly higher than the original resistance, but this increased resistance gradually diminished, as may be seen by comparing the last figure of one line with the first of the next, and perhaps, if time were given, it would return to its original value. There is little doubt that this is a thermo-electric effect.

TABLE VII.

Same arrangement as in Table VI., with a resistance of 300 ohms between battery and bridge.

Since, as is well known, the resistance of a continuous conductor of carbon is diminished by heat, it might perhaps be supposed that the diminution which the resistance of carbon contacts exhibits under the influence of increased currents is due simply to the heating effect of the current. Experiments made with the view of testing this hypothesis failed, however, to support it. The carbon balance, with a weight of 2 grammes in the scale-pan, was placed in an air-bath, the bulb of a thermometer being very near the points of contact; the temperature was slowly raised, and the resistance was from time to time measured in the ordinary way. At 16deg. (the temperature of the room) the resistance was 9 ohms. As the temperature rose the resistance varied irregularly, increasing, however, on the whole, and never becoming less than it was at first, until at 50deg. it had become 10·7 ohms.

The experiment was repeated with a weight of 10 grammes in the scale-pan. The resistance at 17deg. was 4·7 ohms. As in the former case, the resistance rose and fell irregularly as the temperature increased until 31deg., when it was 4·7 ohms—exactly the same as at first. From this point it increased with great steadiness and regularity to 5·7 ohms at a temperature of 50deg.

It seemed possible that the irregularities in the results might be due to expansions and contractions of the steel beam of the balance, owing to which the upper carbon would be caused to slide over the lower, and thus form fresh points of contact of different resistances. Another arrangement was, therefore, made, which is shown in Fig. 4. Across a fixed carbon rod, 6 mm. in diameter, was suspended a smaller piece, having attached to it a wire of the shape shown in the figure, which dipped into a mercury cup. The total weight of the top carbon and the wire was made equal to 1 gramme.

The resistance of this combination at a temperature of 15deg. was 11·9 ohms. When the bath was heated, the resistance at first began to fall steadily, becoming 11·4 ohms at 20deg., but from this point it again rose, and with some irregularities continued to rise until a maximum of 15·6 ohms was reached at a temperature of 36deg. The bath was then left to cool. As the thermometer fell, the resistance at first rose for a short time, being 16 ohms at 34deg. Then it fell with great steadiness and regularity to 14·2 ohms at 24deg., when the observations were discontinued. Other similar experiments were made, with equally inconclusive results. So far as they are worth anything, they tend to show that the resistance of a carbon contact is increased, instead of being diminished, by heat.* This may possibly be due to the formation of

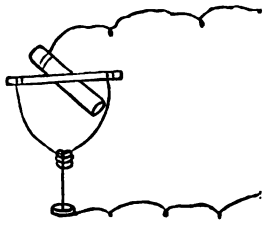

FIG. 4.

a non-conducting film by air or gases which the heat expels from the carbon. The reduction apparently produced by current in the resistance of the contacts is probably quite unconnected with its heating effect, and may be due in part to increased electromotive force.

Under certain circumstances the current appears to produce a permanent and not merely temporary effect upon the resistance; that is to say, the resistance of the contacts is found to be lower (or higher) after the current has ceased than it was at first. The following are a few typical cases:—

A weight of one gramme being in the scale-pan, the resistance of the contacts with a small current (one or two milli-amperes) was 10·5 ohms. A current of ·15 amperes (measured by a tangent galvanometer) was then passed through the carbons for ten seconds. On afterwards testing with the small current, the resistance was found to have fallen to 5·8 ohms. The carbons were then separated by gently raising the scale-pan for a few moments, and carefully replaced in the same position as before. The resistance was now 10·6 ohms, or almost exactly the same as at first. With 5 grammes in the scale-pan, the same current reduced the resistance from 6·6 to 4·3 ohms. With 10 grammes the resistance was permanently reduced from 4·7 to 3·4 ohms, and with 50 grammes from 2·4 ohms to 2 ohms. All these effects were produced by a current of ·15 ampere. Stronger currents (up to a certain point) effect greater reductions.

But when the proportion of the current strength to the pressure at the points of contact exceeds a certain limit, the effect of the current is apparently to produce a permanent *increase* in the resistance, and this increase is sometimes very considerable. Thus, for example, with a weight of 5 grammes the resistance was 6 ohms; after a current of ·6 ampere (four times as strong as in the preceding experiments) had been passed through the carbons for ten seconds, the resistance, measured with a small current, appeared to be about 200 ohms, falling in three minutes to 35·9 ohms. These latter measurements, however, afterwards turned out to be partly illusory; for a tangent galvanometer, placed in circuit with the carbon, shows that the effect of a current beyond a certain strength is really to render the resistence infinite, or at least very great. The resistance does not rise gradually, but suddenly, generally after the circuit has been closed for from two to ten seconds, and at the moment of the rise a minute flash of light appears at the points of contact. The galvanometer needle suddenly goes to zero, and when this has occurred no deflection whatever is produced on opening and closing the circuit with a key. A slight vibration, however, partly or wholly restores the conductivity of the carbon, and, curiously enough, the

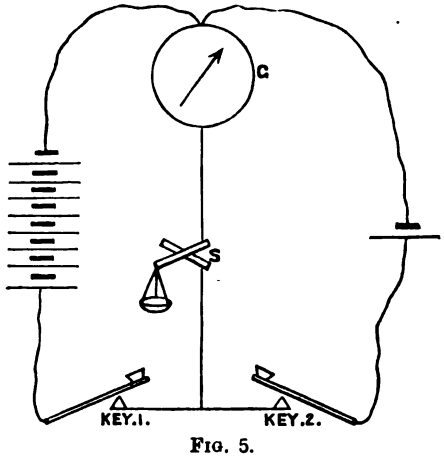

FIG. 5.

ame effect is often produced by the feeble current used to measure the resistance. Thus it may happen that, while the moment before measurement the resistance may be infinity, the very act of measurement reduces it to a few hundred ohms.

This curious effect is best shown by the special arrangement indicated in Fig. 5. G is the tangent galvanometer, S the carbon balance, in the

* I take it as being beyond dispute that the resistance of a *continuous* carbon conductor is diminished by heat. A Swan lamp being placed in the air bath, the resistance of the carbon filament steadily fell from 80·9 ohms at 19deg. to 76·5 ohms at 100deg., following the received law.

Digitized by Google

scale-pan of which is a weight of one gramme. When key 1 is depressed, the current from 8 Leclanché cells passes through the galvanometer and the carbons. The immediate effect is a deflection of (in the case of the galvanometer used) about 75deg. Almost instantly, however, the needle returns to zero, and key 1 may be now raised and depressed without producing the slightest movement of the needle. If, however, key 2 is depressed, it frequently happens that the current from the single cell will pass through the galvanometer and the carbons, producing a small deflection of from 2deg. to 10deg. But if key 1 is once more depressed, the needle again altogether fails to move.* The resistance at S is therefore of a very peculiar nature, being more easily overcome by a small electromotive force than by a high one. Though I have successfully performed this experiment some scores of times, it occasionally happens that the single cell is as powerless to overcome the resistance as the larger battery.

The group of phenomena last described were now investigated systematically. In the first place the arrangement shown in Fig. 6 was used, the

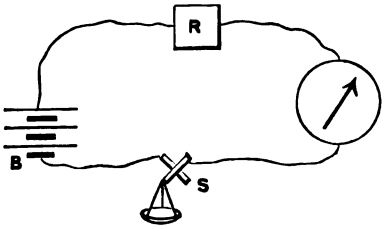

FIG. 6.

carbon balance, a tangent galvanometer, and a box of resistance coils being arranged in simple circuit with a battery of 10 Leclanché cells. Various weights were put in the scale-pan, and resistance was gradually taken out of R until the sudden rise in the resistance of the carbon contacts occurred, the galvanometer reading immediately before it went to zero being noted. The results are given in Table VIII., the pressure at the point of contact ranging from ·05 gramme, when the sudden rise occurred with ·02 ampere, to 5 grammes when the rise occurred with ·63 ampere.

TABLE VIII.

Showing for various pressures the smallest current which produced a sudden great rise in the resistance of the carbon contacts.

·5	·37		

It will be remembered that before the sudden rise an increasing strength of current effects a permanent reduction in the resistance of the carbon. For examining this effect the apparatus was arranged as shown in Fig. 7. It is essentially a Wheatstone bridge arrangement, the proportional coils

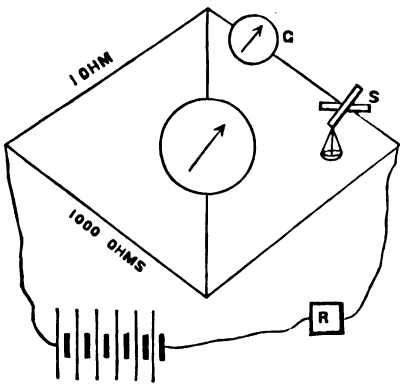

FIG. 7.

used being 1 and 1,000 ohms. A tangent galvanometer of ·9 ohm resistance is inserted in the same arm as the carbon balance, and a box of resistance coils, R, is placed between the battery (which consists of 8 or 10 Leclanché cells) and the bridge. The arrangement admits of the measurement of the resistance of the carbon when traversed by strong currents, the strength of which can be regulated by the resistance box R, and measured by the tangent galvanometer G. A given weight being in the scale-pan, known currents of gradually increasing strength were passed through the carbon. The resistance was measured, 1st, while the known current was passing; 2nd, with a very small current, obtained by unplugging 10,000 ohms in the resistance box. As the currents increased in strength, the resistance, measured with the very small current, gradually diminished until a point was reached—and the lighter the weight the sooner this was the case—at which the resistance suddenly became infinity. The measurements are given in Table IX., the currents varying from ·01 to ·7 ampere, and the pressures from ·05 gramme to 5 grammes.

* In order to avoid the effect of possible vibration, the keys should not be on the same table as the carbon balance.

(TO BE CONTINUED.)

THE EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY (LIMITED).

The nineteenth ordinary general meeting of this Company was held on Wednesday, the 18th inst, at the City Terminus Hotel, Cannon-street, under the presidency of John Pender, Esq., M.P. The secretary (Mr. F. E. Hesse) read the notice convening the meeting, and the minutes of the eighteenth ordinary general meeting, held November 1, 1882, which were confirmed, and signed by the chairman.

The CHAIRMAN: You have had the report in your hands for some time. I presume you will take it as read. Well, I shall refer to some of the leading points in the report, so that I may show you clearly the fluctuations during the past six months. The gross receipts for the half year have amounted to £209,131, against £205,963 for the corresponding period of 1881, or an increase of £3,168. The working expenses are £54,782, against £51,643 for the corresponding period, or an increase of £3,139. This is principally caused by station expenses, showing an increase of something like £1,400, in consequence of larger travelling expenses having been incurred in bringing home and shifting about the foreign staff, and through the cost of repairs to the cables being £1,200 in excess of that in the corresponding period. The net revenue has been £110,755, against £76,970, showing an apparent increase of £33,785. But during 1881 a sum of £34,000 was taken from revenue towards the renewal of the Batavia cable, to which I fully referred at the last and the previous meetings, consequently the net revenue for the half year under review is practically the same as it was during the corresponding period of 1831. If, however, the figures for the whole year are considered, the following satisfactory results are shown:—Gross receipts of 1882, £416,250, as against £397,543 in 1881, giving an increase of £18,707. The working expenses of 1882 were £105,137, as against £105,741 in 1831, showing a decrease of £604 for the year [applause]. The net revenue for 1882 was £194,148, as against £171,725 in 1881, showing an increase of £22,423 [applause]. For the past half-year 1½ per cent. dividend, amounting to £24,968 15s., has been paid, and it is now proposed to distribute another dividend of like amount, together with a bonus of 2s. per share, which, with the previous payments for the first half, will make a total distribution of 6½ per cent. for the year 1882, as against 6 per cent. for 1881. The sum of £64,311 has been added to the reserve fund for the year, increasing that fund to £351,033. I may mention, gentlemen, that since these accounts were printed we have invested a further £100,000 for the reserve fund, which will appear in the next half-yearly statement. £50,000 of this is from the earnings of the Company, and £50,000 is the premium which we made upon the issue of our new shares, so that you will observe that our reserve is getting to a very goodly sum indeed. A sum of £30,000 has also been taken from revenue during the past year, besides £34,000 in the previous year, towards the renewal of the Singapore-Batavia cable, but for which the reserve fund might have been further increased by that amount, or a portion of it applied to increase the dividend, and the balance carried to the reserve fund. We have also spent out of revenue during the last four years, in addition to the sums already alluded to, £35,585 in renewing various portions of the Company's cables, involving an expenditure of 1,800 knots of cable. At the same time we have picked up 1,600 knots, which have been taken into the cable account at a depreciated value before arriving at this result. All this has been done to improve our system and to strengthen our position as a dividend paying concern. Our system now consists of 11,250 knots of cable, of which about 1,800 knots are more or less exposed to the action of the teredo. This, you will understand, has been the little foe we have had to fight, and it has been persevering to a degree which it is almost difficult to explain. But I think we have conquered it at last. I think with the ribbon cable—this yellow portion of the cable (exhibiting a piece of the cable to the shareholders)—we have so far been able to beat our enemy. We have done this, so far, entirely out of revenue. We have not added one shilling to capital in improving our system—in taking up what was bad and replacing it with what we consider an armour-plated cable against the teredo. Of the 1,800 knots of cable more or less exposed to the action of the teredo, 825 knots have been replaced by brass-ribboned cable, leaving nearly 1,000 knots still to be replaced, and we propose doing this as opportunity occurs, putting in new pieces, and taking up the old, and we shall be able to utilise the portions picked up in other directions. I may mention that the shares we issued (50,250) were readily taken up by the shareholders at £1 premium, and since the report was issued the committee of the Stock Exchange have granted a special settlement and quotation for the shares. Now I think, so far as figures go, I have shown you a very good account of your affairs, and I think I may say, looking to the fact that we have so far secured ourselves against the teredo, that with the amount we have now got to the reserve, and with the almost immediate prospect of seeing our reserve fund stand at half a million sterling, I think it is, perhaps, not too sanguine to say that if we have the same success during the next six months that we have had during the last year we may probably be able to add as much to the dividend next year as we have done in the past year [applause]. Now, gentlemen, there is a question that comes up which is personal to the Board and myself, and which you will observe is referred to in the report. Some 18 months ago Colonel Glover died. He was then managing director of the Company, and in receipt of £1,500 a year. I stated on that occasion that, constituted as we were, I hoped we should be able to conduct the affairs of the Company with perfect satisfaction to all concerned without appointing a successor. I think I may say we have done so very successfully, for perhaps in no period of the Company's history has it been more successful than it has been during the past eighteen months. And I may say that the managing direction, so far as it goes, involves a day to day, if not an hour to hour attendance on the part of myself and those around me whom I choose to call to my assistance at any time, and who are always ready to respond. The affairs of the Company have been carried on in such a way that we think we are justified, having saved in the first place £1,500 a year,

Digitized by Google

in having reverted to the original sum which was granted to the directors, viz., £4,000 a year. We reduced that amount for a considerable time, as you are all aware, when we were not paying as high a dividend as we considered we ought to pay. But now that we are giving I hope not a very excessive but a fair and increasing dividend we think it is not unjust that we should share with you a little of the prosperity. Therefore, I think it better to be straightforward, and to tell you exactly the reasons that we have for doing it, and I hope that as our affairs are altogether prosperous you will not grudge that which we have taken the liberty of placing into the accounts—in other words, of reverting to that which we had a right to, but which we gave up for a time [applause]. Now, gentlemen, during the year we have had several repairs, as usual. If we could only do away with those repairs I cannot tell you what good we might do, and how much benefited you would be; but, after all, we must meet them, and fortunate we are in being able to meet them—that is in knowing that we have a property which really, when an accident occurs, we know that we can mend. We have at the present moment (and this shows the enormous importance of duplicating our cable) one of our cables to Australia interrupted. We have just received a communication which will lead us to believe that in a comparatively short period it will be repaired; but for some days it has been interrupted, and in grappling for the one we got the other, and a very singular circumstance occurred. We actually had to take the end of the old cable, attach it to the other end of the new, and carry on the traffic for some time in this manner. You see when we lay a cable in the depths of the sea it is not easy to say where it will be twelve months hence. At all events, we have found that cables have drifted five or six miles from the point indicated on the chart. Still, all this shows that we have a property which we can control and repair when accidents occur. Now, there is another important point I have to mention. Since I last had the pleasure of addressing you we have carried out a very successful enterprise in establishing a line of cable from Hong Kong to Shanghai. When this Company was originally formed it was our intention to make our northern terminus at Shanghai. But when we had laid our cable from Madras to Penang, Singapore, Cochin China, and Hong Kong, intending to carry it on to Shanghai, we were more or less anticipated by the Great Northern Company, whose line passes through Russia, and who share with us the China traffic at the present moment, by their laying a cable between Hong Kong and Shanghai. We felt they were trenching on our ground. We intimated this to the Great Northern Company, and they prudently, I think, took our view that where one cable would do the work there was no use laying down a second one. We therefore came to an arrangement with the Great Northern Company by which we shared with them the benefit of the cable they had laid down. That has continued now for twelve years. We have found from experience that one cable does not give the permanent service which we now desire to give to those who use the submarine telegraph, and there was a very strong expression of opinion among the commercial community of Shanghai and Hong Kong that the existing service was not satisfactory, and they threatened to form a co-operative company for the purpose of laying and working a cable of their own. I felt that this would be an interference with our rights, and putting two links in a chain where one was quite sufficient for the continuity, and therefore I at once communicated with the Great Northern Company, stating that the time had now come when it was necessary that this system should be duplicated by a cable to be laid and worked by our Company. There was great opposition on the part of the Great Northern Company to our establishing this line to Shanghai, but we had made up our minds. We had ordered the cable, and we sent our ship off. The result was that negotiations took place. The old treaty was re-considered, and we have now entered into a fresh one with the Great Northern Company for a considerable number of years by which we, the Eastern Extension Company, are to share with them what we did not before, namely, all the privileges which they hold north of Shanghai and the Japanese traffic. We were very decided about having our terminus at Shanghai, for the simple reason that within the last two or three years China has given very marked evidence of making progress in the direction of European civilisation, and if China is opened up, and if the telegraph system which the Chinese are projecting is carried into effect, it will be a wonderful feeder of our system. We therefore felt that if we gave up Shanghai we should give up a very great hold upon traffic which we considered we were entitled to have—because the English trade at the present moment with China is something like 80 per cent. of the whole traffic. Consequently we felt that it would be impossible for us to allow that traffic to pass into hands which might, in some measure, retard the commercial relations between the two countries in the way we shall always endeavour to promote by our grand system of international telegraphy. The result of the whole thing has been that we have entered into this arrangement with the Great Northern Company, and our cable is now laid. We have had difficulties to encounter; not so much in landing it, but as to the point at which we ought to land it. I think, however, that in a few days these difficulties will be overcome, and our system opened for traffic, and I look for a considerable profit from this important negotiation, and if the arrangement is loyally carried out, I believe it will benefit not only the two companies, but also those who are telegraphing from China to Europe, by giving a more permanent, certain, and better system. I think, at the same time, that China will be benefited. There is just one other point before I leave China. We have an important station at Hong Kong, and the Chinese are likely to carry to Canton the land line system they are now projecting, and we have made arrangements whereby we shall connect with that system, and work the telegraph coming from China to Canton and Kowloom—the border where Chinese territory ends and English territory begins. Therefore, looking at it all round, I think we have in our grasp all that vast system of telegraphy which, if well used, will be beneficial to all. There is another movement that we have made since I last had the pleasure of addressing you. We have entered into negotiations for carrying our system from Penang to Bangkok, the capital of Siam. We have obtained a concession for forty years, which ought to give us, at all events, a traffic that will pay for the expense we are going to incur in carrying out this work. It will not be a very large feeder, but I think it will strengthen our hands still more. I trust that the next time I have the pleasure of addressing you I shall be able to state that this connection has been completed. With these remarks, gentlemen, I beg to move, "That the report and accounts of the directors now submitted be received and adopted, and that a dividend be now declared of 2s. 6d. per share, together with a bonus of 2s. per share, both free of income-tax, payable on the 18th inst., making, with the previous distribution, a total payment of 6½ per cent. for the year 1882."

The Marquis of TWEEDDALE: I have much pleasure in seconding that.

The CHAIRMAN: Now, gentlemen, before I put that resolution, if any shareholder in the body of the hall has anything to say I should be very glad to listen to him, and to give the best reply in my power to any point raised.

Mr. GRIFFITH: I am sure that we must feel obliged to you for your lucid statement, and we must all be gratified at the announcement that the reserve has now attained to such a sum that we may hope in the future to have an increased dividend in addition to that paid on the present occasion. I have been looking over the accounts, and there was one point that occurred to me, namely, that our reserve fund does not produce much beyond 3 per cent. Of course, our reserves ought to be invested in good securities; but it does occur to me, now that we have so large a reserve fund, whether it would not be desirable in future, instead of adding to that fund, to use our surplus revenue in paying off some of our debentures. I put this rather tentatively than otherwise, as I know that debentures are drawn in different forms. Some are drawn as debenture stock, others as debentures that must run for a certain number of years, and in other cases they are drawn as debentures payable to bearer. As we pay 6 per cent. and 5 per cent. for our debentures, and only receive a little over 3 per cent. from our reserve fund, it seems to me that it might be advantageous if, in the future, we were to pay off some of those debentures (this is on the supposition that there are any payable to bearer), and so save a large amount of interest every year. That would increase our income by the mere exercise of an economical arrangement, and would not in any way prejudice us, for we have already a reserve fund which will shortly amount to £500,000, and we may look to the position of the Company as a stable one, the dividends of which will be progressive, and largely in excess of the dividends paid in the past. There was another point you have referred to in connection with the death of Colonel Glover. We are glad to find that the Board are able to carry on the business as successfully as in former times, and that both the stability and business of the Company are increasing. We find by the report that the receipts are in excess of what they were last year, and your statement shows reasons for our expecting a still greater excess. We may congratulate ourselves upon this state of matters, and I think it would be very unfair on our part if we declined to give a share of our prosperity to those who have been instrumental in bringing about these most satisfactory results. I think we are not only indebted to you for the last dividend, but for the intelligence displayed in connection with the future of the Company by bringing us into relations with a country that is now adopting habits of civilisation—China. I have had the pleasure of meeting the ambassador of that country, and I can say that the desire of the educated classes of China is different now to what it used to be. Before, they were exclusive, but they are now adopting many of our principles of international law, and principles of policy, and anything that we can do to add to their benefit will be advantageous not only to them but to us. I hope we shall show our gratitude to the directors by consenting to the remuneration mentioned.

The CHAIRMAN: Gentlemen, you have heard Mr. Griffith's remarks upon the financial position of the Company. We are watching this very closely, and as our 6 per cent. debentures will expire by and by, we hope to replace them at a lower rate of interest; but, notwithstanding that, I do not think it would be prudent to lose sight of the reserve fund. It is a grand stand-by. You could not have your shares at their present premium if you were to wipe out the reserve fund even in the manner suggested by Mr. Griffith. I speak with the most perfect confidence as to our telegraph system. Still, I feel if we had to renew any part of it, it would be a grand thing to have our reserve fund to fall back upon. However, I think when we get it up to such a point as half a million, or more, probably the interest upon it might form a portion of the dividend; in other words, that those who are shareholders would derive some profit out of the investments, because we shall always continue to add something to it. If there were a decent sum of interest amounting to half or one per cent., and the shareholders were getting that paid to them out of this reserve fund, it would give them, as it were, two strings to their bow. You would have not only your dividend from this large reserve fund but also from the working of the system.

Mr. JOHN NEWTON: I should like to say one word. I have so often criticised the policy of the Board that I wish to say that I thoroughly appreciate the principle of the Board taking additional remuneration when they have increased our dividend beyond 6 per cent. I am sure the shareholders will not object to pay the directors handsomely when they pay us so good a dividend, and moreover when they promise to pay us even more. You deserve your remuneration in this Company. I do, however, object to the principle of doing away with the managing director. I think a company that has four millions of capital and such a great organisation as this should not be dependent on the life of any one single man, and I do not, sir, admit the principle that your colleagues can take your place at a moment's notice. If they could take your place they could not take the place of a managing director, and it is establishing a wrong principle to my mind to say that you can do without a managing director. If you can do so the other companies can, and that is, I believe, a wrong principle. There should be not only a chairman who takes a very active interest in the Company, but another director to whom the shareholders can look for a large amount of responsibility for the whole organisation—the complete establishment, and the staff; and, therefore, I do think this Company can well afford to pay a managing director handsomely, as well as to pay the Board handsomely when they are giving the shareholders such results as you are giving us, and when you can promise and show us such a prospect of improvement as this Company shows. If you are not now standing at the head of all the telegraphs of the world, I feel that you will soon do so, but I think it would not be prudent for the sake of £1,500 a year to do without the services of a capable and efficient managing director.

The CHAIRMAN: I shall not enter into a discussion upon the views which Mr. Newton has just expressed. All I can say at the present moment

Digitized by Google

is that there is a great deal to be done still before we get the system thoroughly completed, and there is a great deal to do that not only requires the daily and hourly attention of your chairman, but also of the other members of the Board on particular occasions. We are working in perfect harmony just now. I have great respect for the opinion that Mr. Newton has expressed in reference to one of our companies. We have carried on that system with wonderful success, viz., in having Sir James Anderson as managing director of the Eastern Company. But at the present time we have such a combination in being all under the same roof that we utilise the good heads round about us, and if we can do that and save a considerable amount of money to the shareholders, I think we are perfectly justified in doing so. All I can say is this, if I saw that you were suffering in the slightest degree, or that the interests of the Company were likely to suffer by the course that we are now pursuing, I would at once adopt the suggestion of Mr. Newton. But meantime I am satisfied that we are throwing a greater responsibility on the directors. A managing director takes off a considerable amount of responsibility from his colleagues, and I wish the directors individually, as well as collectively, to feel that there is a responsibility resting on their shoulders, and I do not wish to relieve them from it, at all events, at the present time. With these remarks I ask you to approve of the resolution I have placed before you. To the contrary. Carried unanimously. I should just say one word with regard to the directors' remuneration. Mr. Newton has been kind enough to criticise—and criticise us very justly. In fact, there is nothing I like so much as good hard criticism, and he has given it us from to time very fairly, and sometimes we have thought a little too hard. But at all events we the more appreciate Mr. Newton's remarks to-day in that they have come from a quarter where the part of the watch dog has been played throughout, and as Mr. Newton approves of what we have done to-day I think we may safely congratulate ourselves on having done that which the general body of the shareholders quite approve.

The Marquis of TWEEDDALE: I have the pleasure of proposing the following resolution, which I am sure you will adopt unanimously:—"That John Pender, Esq., M.P., who now retires by rotation be and is hereby re-elected a director of this Company."

Sir WILLIAM MCARTHUR, K.C.M.G., M.P.: I second the resolution.

The Marquis of TWEEDDALE put the motion, which was carried unanimously.

The CHAIRMAN: Gentlemen, as they say in Scotland, one good turn deserves another, and I have now the pleasure to propose, "That the Most Honourable the Marquis of Tweeddale, who now retires by rotation, be and is hereby re-elected a director of this Company."

Mr. FRANCIS AUGUSTUS BEVAN: I have great pleasure in seconding the resolution.

The CHAIRMAN put the motion and declared it carried unanimously.

The Marquis of TWEEDDALE: I beg to thank you.

The CHAIRMAN: Now, gentlemen, the next resolution will be moved by Mr. Abbott.

Mr. WILLIAM ABBOTT: The resolution has reference to the auditors, and as I do not wish to speak twice, I may say at once what I wish to say as to the question raised by Mr. Griffith in relation to the reserve fund I think that, great as has been your skill in the administration of this Company from time to time, and the recommendations which you have made to the shareholders, which I well remember were vigorously opposed by certain sections of the shareholders, who, by the by, I do not see here to-day, it is well that I should, having some knowledge of this matter, commend you for the care and skill with which you have selected your investments forming the reserve fund. I differ from Mr. Griffith, who says you only get about 3 per cent. return on the investments. You derive considerably more than 3 per cent., and moreover there is a considerable profit on what those investments originally cost you. That is a point very satisfactory to the proprietors. With regard to the suggestions that you should diminish your reserve to pay off your debentures, I cannot imagine any system of finance more ruinous to a company like this, which, to a great extent, like other trading companies, depends largely on its credit. With these remarks I move the re-election of Mr. Henry Dever and Messrs. Quilter, Ball and Co., at a remuneration of £100 each. I wish to inform the shareholders, as I take the responsibility of moving this resolution, that the remuneration is an increase of £50 to each auditor. I think with the increased capital, and the constant progress of the concern, the care they are obliged to exercise over the securities, and the advice which they have, no doubt, to give the Board on many matters, it is only right that we should increase the remuneration of the auditors. They have done their work fairly and well, and it is only right that they should be paid accordingly.

Mr. MARCUS seconded the motion, which was carried.

Mr. ABBOTT: Before we separate I wish to move a hearty vote of thanks to the chairman and directors. The chairman has said that they are all working together harmoniously, and that they avail themselves from time to time of the value of the heads that are under the same roof. I hope, however, they will not draw too much on the brain of Sir James Anderson, for I should be sorry, indeed, to see him deteriorate from the handsome appearance he always presents [laughter]. I propose a hearty vote of thanks to the directors.

Mr. MARCUS: I beg to second the motion.

Mr. ABBOTT put the motion, which was carried.

The CHAIRMAN: There is nothing so pleasant to your Board as to be able to pay an increased dividend and receive your thanks and increased confidence. I beg to thank you on the part of the Board.

Mr. STOKES: I think we should propose a vote of thanks to our secretary and staff, who are helping the directors so well.

The CHAIRMAN: I am quite sure that they will appreciate your kind thought of them, and I can assure you that we do not lose sight of them in the arrangements that we are now making.

The proceedings then terminated.

NUMBERS OF "THE ELECTRICIAN" OUT OF PRINT.—The following numbers of *The Electrician* are out of print, and cannot be supplied at the office, viz.:—Vol. 1, Nos. 3, 9, 19; Vol. 7, Nos. 8, 10, 12 to 18, 20, 21, 24 to 26; Vol. 9, 1, 3, 6 to 12, 15 to 26; Vol. 9, Nos. 2, 4, 24, 25; Vol. 10, No. 13.

IN the HIGH COURT of JUSTICE, CHANCERY DIVISION.

IN the MATTER of THE COMPANIES' ACTS, 1862 and 1867, and IN the MATTER of the PHŒNIX ELECTRIC LIGHT and POWER COMPANY (Limited).

The Creditors of the above-named Company are required, on or before the 10th day of May, 1883, to send their names and addresses, and the particulars of their debts or claims, and the names and addresses of their solicitors (if any) to HENRY BISHOP, of 41, Coleman-street, in the City of London, the liquidator of the said Company, and if so required by notice in writing from the said liquidator, are by their solicitors to come in and prove their said debts or claims at the chambers of Mr. Justice Pearson, at the Royal Courts of Justice, Strand, in the county of Middlesex, at such time as shall be specified in such notice, or in default thereof they will be excluded from the benefit of any distribution made before such debts are proved.

Wednesday, the 23rd May, 1883, at 12 o'clock at noon, at the said chambers, is appointed for hearing and adjudicating upon the debts and claims.

Dated this 11th day of April, 1883, E. W. WALKER, Chief Clerk.

Freshfields and Williams, 5, Bank-buildings, London, E.C., Solicitors for the Liquidator.

TO TELEPHONE COMPANIES, &c.—ELECTRICAL ENGINEER and MANAGER.—A GENTLEMAN (aged 30 years) holding Certificates of Qualification from Royal College of Science is open to accept an APPOINTMENT as ENGINEER and MANAGER. Advertiser has had an excellent business training, and could undertake the general management of a Telephone Exchange.—Address, E. M. F., this office.

WANTED.—VOLS. VII. and VIII. of "THE ELECTRICIAN," either bound or in parts. Address, stating price, B. B. H., HARRISON and SONS, 45, St. Martin's-lane, London, W.C.

A GENTLEMAN, thoroughly acquainted with the theory and practice of electricity, wishes for EMPLOYMENT.—J. KING, 15, St. John's-square, Clerkenwell, E.C.

WANTED EMPLOYMENT in LONDON, either paid or unpaid, upon dynamo-machines, by an electrical student, with no practical experience, but ready to make himself useful. Address, W., 21, Herbert-street, New North-road, N.

ELECTRIC LIGHT and POWER.—The Advertiser (Mem. Soc. Tel. Eng.) will be disengaged in June next, wishes an English or foreign APPOINTMENT. Accustomed to erection of machinery and installation of works.

X. Y., office of ELECTRICIAN.

WANTED, ELECTRICIAN and ENGINEER by provincial Electric Lighting Company. Must be skilled in installation work, in practical use of tools, and possess good knowledge of the construction of electric light apparatus; also able to take general management. Salary as arranged, not to be less than £150. Applications, with full references and certificates, to M. A., office of THE ELECTRICIAN, 396, Strand.

SLIP

THE HAMMOND ELECTRIC LIGHT COMPANY.—The second ordinary general meeting of this company will be held on the 9th May.

ELECTRIC UNITS.—On Thursday, May 3, Sir W. Thomson, F.R.S., M.Inst.C.E., will lecture at the Institution of Civil Engineers on "Electrical Units of Measurements."

CRYSTAL PALACE MANAGERSHIP.—Mr. G. G. Cleather, assistant-manager, has been appointed manager of the Crystal Palace, in the room of the late Mr. G. W. Reay-Mackey.

THE INSTITUTE OF CIVIL ENGINEERS.—This institution now numbers 21 honorary members, 1,347 members, 1,671 associate members, 524 associates, and 774 students, making altogether 4,337.

NEW COMPANY.—The McTighe Electric Light and Manufacturing Company has been incorporated, with a capital of 300,000dols. They are going to erect a large manufactory in Pittsburg, Pennsylvania, U.S.

THE EDISON SYSTEM IN ENGLAND.—The Edison Company of London had installed up to April 6 no less than 4,463 lamps, whilst the Manchester company's installations numbered 3,980, making a total for England of 8,443.

THE SINGAPORE-SAIGON CABLE REPAIRED.—The Eastern Telegraph Company notifies the restoration of the Eastern Extension Company's Singapore-Saigon cable. Messages can again be accepted for China, Japan, Manila, and Cochin China, "*viâ* Eastern."

THE EDISON SYSTEM AT THE AQUARIUM.—The Edison Company have replaced the B or eight candle lamps hitherto shown at the Aquarium Exhibition by A or sixteen candle lamps. The new lamps have a much better effect than those formerly in use.

"JOURNAL OF THE SOCIETY OF TELEGRAPH ENGINEERS."—The present number of this journal contains Mr. Shoolbred's Paper on "The Measurement of Electricity," Mr. Munro's Paper on "Telephone Transmitters," and other matter of interest.

THE TELEPHONE IN THE WEST INDIES.—The question of introducing the telephone into Georgetown, British Guiana, has for some time past been under discussion. It is now stated that a scheme for the establishment of a telephonic exchange there has been adopted.

REPAIR OF THE ZANZIBAR-MOZAMBIQUE CABLE.—The Eastern Telegraph Company announce the repair of the Eastern and South African Company's cable between Zanzibar and Mozambique, thus re-establishing telegraphic communication with the Cape of Good Hope and Natal.

HONOURS FOR AN ELECTRICIAN.—In announcing last week that Dr. Siemens had been made Sir C. W. Siemens we omitted to state that another well known electrician had had a similar honour conferred upon him by Her Majesty the Queen. Prof. F. A. Abel will in future be known as Sir F. A. Abel.

SECONDARY BATTERIES.—On the evening of May 7 Mr. C. T. Kingzett, F.I.C., F.C.S., will read a paper on "Secondary Batteries" before the Society of Chemical Industry at Burlington House. It is understood that he will, incidentally, give a description of his own improvements in secondary batteries.

CHANGES OF ADDRESS.—The Hammond Electric Light and Power Supply Company have removed their Lancashire offices from 36, Dale-street, Liverpool, to 79 and 80, Hawarth's-buildings, Cross-street, Manchester, the business still being carried on under the general management of Mr. James Shaw as heretofore.—The Vulcanised Fibre Company (Mosses and Mitchell) have removed to their new premises, 68, 69, 70, and 71, Chiswell-street, Finsbury, E.C.

A NEW CABLE.—The Eastern Telegraph Company has now completed its triplicate cable through the Red Sea from Suez to Aden. The cable, the successful laying of which was completed at the end of last week, was manufactured by the Telegraph Construction and Maintainance Company, and is of the most recent type, being brass covered, to guard against the attacks of marine insects. The ships employed in the work were the ss. "Seine" and "Kangaroo."

THE LIGHTING OF LIGHTHOUSES.—The committee appointed by the Board of Trade to determine the relative merits of oil, gas, and electricity as lighthouse illuminants consists of Captain Nisbet, of Trinity House, chairman; Dr. Ball, F.R.S., Astronomer Royal for Ireland; Mr. A. Vernon Harcourt, F.R.S., Dr. Hopkinson, F.R.S., Mr. J. Crichton, Sheriff of Fife; Sir James Douglass, C.E., and Mr. J. R. Wigham, of Dublin. Mr. E. Price Edwards has been appointed secretary to the committee.

WATER POWER GALORE.—California would appear to afford abundant opportunities for exercising the calculating powers of electricians, whose acme of happiness is to utilise the powers of nature constantly running to waste. It appears that there is a fall in the Yosemite Valley, California, which leaps down 1,600ft. at one bound, while there is a second lower fall of 600ft., and yet a third of 434ft. The Sentinel Fall is said to have even a greater leap still. Beside these gigantic efforts of nature, Niagara, with its puny 163ft. of fall, sinks into insignificance.

ELECTRIC LIGHTING ON SHIPS.—It is stated that the Guion Liner ss. "Oregon," now building at Fairfield Yard, Glasgow, is to be fitted throughout with the electric light, and that a spare set of generating plant is to be kept in reserve for any emergency that may arise. The contract for the work has been concluded between the owners and the Edison Company. Five hundred A (6 c.-p.) lamps will be employed. It is the intention of the Guion Line that the "Oregon" shall beat her sister ship the "Alaska" by six hours, and so still further shorten the trip across the "herring pond."

ELECTRIC LIGHTING IN PENTONVILLE-ROAD.—This road has for some time past been lighted by means of Maxim incandescent lamps, a pair of which are fitted inside each lamp post in place of the ordinary gas burner. It appears that the Clerkenwell Vestry are not at all satisfied with the lighting by the incandescent system, and accordingly the Maxim-Weston Company have offered to substitute 10 Weston arc lamps of 1,500 candle-power for the present lamps, at a cost to the vestry of 4d. per lamp per hour. To this the vestry have agreed, and we believe the change is to be carried out at once.

THE ELECTRIC LIGHT IN OUR HOMES.—Mr. R. Hammond delivered a lecture on this subject in the Albert Hall, Leeds, last week. He drew attention to the many advantages of the incandescent system, and to illustrate his subject exhibited a model drawing room on the stage of the hall, which was lighted by this means. Mr. Hammond informed his audience that he had adopted this light in his own house in London, and that its cost to him was somewhat less than that of gas, although he laboured under the disadvantage of having to produce his current on his own premises, instead of having it distributed to him from a large station.

ELECTRIC LIGHTING AT THE MERSEY TUNNEL WORKS.—As we have already stated in these columns, the electric

Digitized by Google

light has been in use for some time past at the Birkenhead side of the above works. We understand that the contractor, Mr. Waddell, of Edinburgh, is so satisfied with the performance of the lights, that he has had twelve more fitted up on the Liverpool side of the tunnel. The lamps and dynamos are on the Brush system, and have been supplied and erected by the Hammond Electric Light Company of Liverpool, under the superintendence of Mr. James Shaw, district manager, and Mr. Goold, electrician to the company.

M. Marcel Deprez.—We learn that this eminent electrician has had conferred upon him the rank of officer of the Legion of Honour, in consideration of his services to science. His experiments in transmitting power by means of electricity will be fresh in everybody's recollection, and no one will begrudge him the above-mentioned recognition of his untiring energy and zeal. He has succeeded up to a certain point, as readers of this paper know; whether he will be able eventually to make his system entirely successful from a practical and commercial point of view the future alone can show. No doubt it will not be his fault if he does not do so.

Prevention of Fire Risks.—The Society of Telegraph Engineers and of Electricians have just issued their rules and regulations for the prevention of fire risks from electric lighting, in a slightly modified and re-arranged form. The chief rectifications appear to be the omission of the recommendation to fix dynamos on an insulating bed. The committee have also thought well to omit all mention of the best kind of joint for electric light wires, together with the sketch which was given in the old rules, and to content themselves with stating that "joints should be electrically and mechanically perfect, and united by solder." The only other alteration of any consequence that we have noticed is that the maximum electromotive force to be allowed inside buildings, when alternate currents are used, has been raised from 60 to 100 volts.

A Thermoscope.—At the Royal Scottish Society of Arts, a few nights ago, Professor Swan gave a description of his thermoscope. Its construction is as follows:—A small mirror, whose plane is vertical, is carried by a stretched vertical torsion fibre of glass or platinum, and has a short arm projecting from its back. To this arm a fine silver wire is attached by its middle point. The two equal segments of this wire are inclined at an angle approaching to 180 degrees, and are fastened by their ends to a support of some substance, such as glass or platinum, of less dilatibility by heat than silver. By this arrangement even a small change of temperature causes a considerable movement of the extremity of the mirror-arm, consequent rotation of the mirror, and large displacement on a fixed scale of the image of an illuminated wire, formed by rays reflected from the mirror. Temperature indications could thus be read on the scale. The thermoscope was shown in action at the meeting, indicating the fall of temperature inside the receiver of an air-pump when the air was being exhausted; and also the rise of temperature when a light was introduced.

The Commissioners of Sewers.—We understand that the Commissioners of Sewers have requested Mr. Musgrave Heaphy, C.E., to report on the methods of electric lighting for the City. We have no wish to dictate to the City authorities, but we should have thought that such an important body would have called to their aid the best attainable advisers. Mr. Heaphy may be thoroughly competent, but it is difficult to suppose this, inasmuch as his connection with electrical work, and especially with electric lighting, has been of very recent date, and the connection has been from the outside rather than from the inside. It seems to us that the commissioners might have found a trained electrical engineer to advise, and then, instead of having to obtain a further report, as they will probably have to do under the present conditions, their advice would have been thorough in the first case. Why put aside such men as Professor Ayrton, Professor Forbes, Professor Garnett, Professor Lodge, Latimer Clark, Dr. Muirhead, and other well-known men whose lives have been devoted to the study of electrical matters, and whose opinions are really valuable, for gentlemen whose knowledge of electrical work is so recent. There is one question we should like to ask. Is rumour correct in stating that a gentleman standing in the front rank of those connected with electrical matters has declined to act as *collaborateur* with Mr. Heaphy?

The Crystal Palace Electric Exhibition.—On Wednesday evening the diplomas and medals gained by the exhibitors at the Crystal Palace Exhibition of 1882 were presented to the recipients by the Duke of Teck. The awards included ten diplomas of honour granted to those who did not exhibit from trade motives. These were bestowed upon the Postmaster-General, the Secretary for War, the Anglo-American Telegraph Company, the Eastern Telegraph Company, the Telegraph Construction and Maintenance Company, the Submarine Telegraph Company, the South-Eastern Railway, the London Brighton, and the South Coast Railway for the general excellence of their exhibits, Mr. C. F. Varley for his induction machine and condensers, and Mr. R. H. Froude for a dynamometer. In addition to the diplomas the awards consisted of twenty-nine gold, twenty-seven silver, and thirty-five bronze medals. A detailed list of the recipients of these was published in our issue of the 5th August, 1882 (*The Electrician*, Vol. IX., p. 271). Before presenting the awards the Duke made a short speech, in which he showed himself to be familar with his subject. He alluded to electricity as being "for centuries the philosopher's toy," until Volta, Oersted, and Faraday revealed to us its true nature. In connection with the laws governing the action of this mysterious power, he paid tribute to the names of Ohm, Gauss, Weber, Joule, Clerk Maxwell, Sir William Thomson, and others. Speaking of the telegraph and electric light, his Serene Highness quoted a string of names, from Ronalds to Hughes, and Pixii to Edison and Swan, as if they were old friends, as they are to most of us. The Duke was afterwards entertained at a dinner in the Palace, at which many electricians were present.

M. Deprez's Experiments.—After the excellent reports made to the Academy of Sciences in Paris by M. Tresca and his *confrères* on the experiments made by M. Marcel Deprez at the Northern (of France) Railway Company's workshops in February last, we should have thought it impossible for incorrect ideas to exist on the matter. We regret to find, however, that the Paris correspondent of the *Daily News* has still some very hazy notions of what actually was accomplished by M. Deprez during his experiments. This would not matter so much if the correspondent in question would keep his notions to himself. Unfortunately he does not, but spreads them abroad before an innocent public, with the natural result that the latter are deluded by them. In the first place, the *Daily News* correspondent says that the wire in the circuit was 20 kilometers long, that is, it was taken to a village 10 kilometers from Paris, and brought back again. Now, 20 kilometres = about 21,860 yards. Turning to M. Tresca's report, as given in *The Electrician* for March 31 and April 7, we find it there stated that the circuit wire

Digitized by Google

was 17,000 metres, about 18,133 yards long. Then, again, our contemporary's correspondent says:—"The first (dynamo) gave out a 9 horse-power force, and the second (dynamo) rendered half that quantity. The loss of power in transmission is 50 per cent.," &c. What does M. Tresca's report say as to this? "Considering the average of the first six experiments," viz., on the 11th February, "we see," he says, "that 2·03 horse-power was transmitted with an expenditure of 6·21 horse-power at the shaft of the dynamometer, which corresponds to a return of ·327 horse-power." Again: "Summing up, it may be stated that the power actually transmitted to a distance of 8·5 kilometres (about 5·28 miles) over an ordinary telegraph wire of 4 millimetres diameter, according to M. Deprez's method of connecting up the machines, represents a third of the motive power." Now let us turn to his report on the second series of experiments, which took place on the 18th of February, at the same place and on the same circuit. From the tables there given we find that the power actually transmitted was ·318 horse-power, in connection with which figures the report says:—"The attention of makers should be given to these figures, and efforts made to minimise the losses so as to approach an efficiency of 50 per cent." The *Daily News* correspondent evidently delights in dealing with round numbers, but surely he might be a little more accurate.

Another Electrical Exhibition.—We have received an official notice intimating that the Italian General Exhibition will be held in Turin, from April to October, 1884, and that a special section is to be allotted to electricity, to which foreigners are invited to contribute. The exhibits will be classed under the following heads: Statical electricity. Electro chemistry and materials for the apparatus and for electric circuits; batteries, accumulators (storage of electricity), &c., wires, cables, &c., lightning conductors. Apparatus for the study of the electric current. Measuring instruments; apparatus for didactic demonstrations. Application of electricity to the transmission of signals and analogous applications. Indicators at a distance, chronographs, electric meters, electric clocks. Telegraphs, telephones, microphones. Application of electricity to safety on railways; signals, block-systems, &c. Application to the firing of mines, and analogous applications. Application to medicine and surgery. Industrial production of electric currents; magneto-electric machines and dynamo-electric machines. Electric lighting. Transport to a distance and distribution of mechanical energy by means of electricity. Electro-metallurgy and galvanoplastics. Various applications. All applications for space are to be sent in on a special form, and must be in the hands of the executive committee by the 31st August, 1883. Motive power will be supplied gratuitously for the lighting and for the experiments to be made in the galleries and in the gardens by the committee itself. In this case the installation or placing of the conductors also will be provided for, gratuitously. In any other case the motive power will be supplied at a price varying from 30 centimes to 50 centimes an hour and per horse-power, according to the number of hours of work and according to the amount of power required. The transport and installation or placing of the machines and of the apparatus will be executed at the expense of the exhibitors. The committee will take the necessary steps in order to obtain from the railway companies reductions in the rate of prices for the articles destined for the exhibition, which articles, however, must always be forwarded carriage paid.

Telephonic Communication in Leeds.—It is about three years since the telephone was introduced into Leeds. For some time but little progress was made in inducing the merchants to take to the use of the new invention. Gradually, however, it began to be known, and as a consequence used, and the progress made during the past twelve months has been very satisfactory. The "calls" at the National Telephone Company's Exchange, Commercial-buildings, Leeds, for the week ending April 13, 1883, were 3,812, with a total of exchange subscribers of 150, against only 632 "calls" and 90 subscribers for the corresponding period of 1882, or an increase during the past year of 60 Exchange subscribers and 3,180 calls. The Corporation of Leeds was one of the first corporate powers to introduce the system of telegraph communication between the various police stations and the Town Hall. The Watch Committee of the same corporate body have decided to establish telephone communication between the Town Hall and the whole of the police stations in the town instead of the A B C telegraph system now in use. At a recent meeting the Watch Committee accepted the tender of the National Telephone Company, Limited, to connect all the police stations in the town for the sum of £211 per annum, the amount paid to the Post Office for the telegraph system, being, we believe, £215 per annum. The contract includes a connection between the Town Hall and the Telephone Exchange, by which arrangement subscribers to the Exchange urgently requiring the services of the police or fire brigade may communicate directly with head-quarters. Three months' notice will be given to the Post Office authorities to terminate the agreement now in force, and by the end of that time all the telephone lines and instruments will be connected and in working order. The above facts show the increasing demand for, and the opinion the professional and mercantile community have of the utility and, in fact, necessity of telephonic communication in this important centre. The work of connecting the police stations, as also the other works in progress, is now being carried out under the superintendence of the courteous and able local manager and engineer of the National Telephone Company, Mr. W. L. Bishop.

The Devon and Cornwall Electric Light Company.—The hearing of the petition for the winding up this company, presented on the 1st November last by Mr. H. Wherlow, a shareholder, was heard before Mr. Justice Chitty on Tuesday. It appeared that shortly after the presentation of this petition nine actions were brought by shareholders for the rescission of their contracts to take shares in the company, on the ground that they had been induced to subscribe for the same by reason of statements in the company's prospectus falsly representing that the company had the exclusive right of using in the districts therein named the Lane-Fox patents. On the 21st of December last Mr. Cadogan, one of the plaintiffs in the actions referred to, obtained an order on motion for the removal of his name as a shareholder from the company's register, and for the return of the money paid by him in respect of his shares, but the order was stayed pending the hearing of the present petition. The allegations upon which the petition was based were that the concessions granted to the company had been discovered to be not so wide as had been anticipated, that the mis-statements in the prospectus had caused proceedings to be taken by the shareholders, that the company had practically never carried on business and could not carry on business successfully, and that for these reasons, and having regard to the fact that by reason of the claims of the shareholders for the return of their money the assets of the company (including any uncalled capital) were insufficient for its purposes, it was just and

Digitized by Google

equitable that the company should be wound up. Since the date of the presentation of the winding-up petition, and of the successful motion, the actions against the company by its shareholders had increased to 35 or 37, and the plaintiffs, including Mr. Cadogan, strenuously opposed the winding up of the company on the ground that the statutory effect of the winding-up order would be to place them in the same position as the contributories who had brought no actions, and who had not been deceived by or had acquiesced in the prospectus; while if the petition were dismissed Mr. Cadogan, who had made out his case, and any other of the plaintiffs who should succeed in making out their cases, would rank as creditors against the company for the value of their shares. The petition was unanimously supported by all the shareholders other than those who had brought actions against the company.—Mr. Justice Chitty said that the truth of the allegations in the petition had been made out by the petitioner. As regards the actions brought by Mr. Cadogan and others Mr. Justice Chitty said that although the misrepresentations in the prospectus amounted in law to a fraud by the company, yet in fact the company was not their author, the true author being the hand who drew the prospectus. It was therefore legitimate for the company to say that so far as the company consisted of individual shareholders it was innocent, and that the proper way of meeting the case of all parties was to obtain a winding-up order. His lordship was satisfied that the petition had not been collusively presented. He therefore made an order for the compulsory winding up of the company, with usual costs.

The Vienna Exhibition.—Since our last note on the applications for space at this exhibition we have received information from the organising committee, giving the names of numerous other intending exhibitors. S. Schuckert, of Nürnberg, will show his dynamos and a rock-drill actuated by electricity; Hermann Sedlaczek lamps, dynanometers, &c.; Alexander Kovaco, of St. Petersburgh, will exhibit electro-plating in all its branches; C. R. E. Menges, of Hague, dynamo machines, measuring instruments, electric lamps and clocks, &c. This exhibit will also include the transmission of power by means of electricity, when it is said that Mr. Menges will show several novelties in the construction of dynamos for this purpose. Paul Rebikoff, of Moscow, has promised to show a new dynamo for feeding differential lamps, also measuring instruments, telephones, &c. A. Bornhardt, of Brunswick, will be represented by blasting apparatus in which the electric current is utilised. Professor Fleeming Jenkin, of Edinburgh, intends to exhibit his system of telpherage, for which he has recently taken out a patent; while Professors Ayrton and Perry will show a model of their electric railway. Messrs. J. Coxeter and Son will have a miscellaneous exhibit of telephones and other electrical apparatus. Amongst the French exhibitors will be found the Société Gramme, the Compagnié Pour L'Eclairage Electrique, Jablochkoff system, and the Compagnié Electrique. F. O. R. Götze, of Leipzig, will exhibit vacuum tubes (Crookes's), an apparatus of De La Rive's for showing the rotation of electric light around a magnet, and a phosphoric apparatus of Dr. Puluj's, a Viennese electrician. The Duplex Electric Light Company, of London, are to show their batteries, which have recently been made public here. Messrs. Felten and Guilleaume, of Mülheim-on-Rhine, will be well represented in their own particular department of cables and wires of all classes. The India Rubber, Gutta Percha, and Telegraph Works Company, of London, and Persan-Beaumont, France, will also exhibit. Amongst the other names we notice those of G. B. Pirelli and Co., of Milan, T. O. Monchel, of Paris, W. Bauer, of Paris, G. Montefiore Levi, of Anderlecht, near Brussels, the Telegraph Construction and Maintenance Company, Walter T. Glover and Co., of Manchester, and the Electrical Power Storage Company, of London. This latter company have promised to send a number of their accumulators—the Faure-Sellon-Volckmar—to the exhibition, and also a boat driven by current supplied by these accumulators, which is to ply regularly on the Danube during the course of the exhibition. From still later information than the above we learn that the German Government have consented to exhibit, and that preparations to this end have already been begun in the various departments of that empire, which deal with the many applications of electricity. Also that the north-east gallery of the Rotunda, where the exhibition is to be held, will be fitted up as a suite of rooms on the furnishing and decoration of which all the art and skill of Viennese cabinet makers will be expended. The rooms will be lighted by incandescent lamps with the special object of showing the adaptability of this system to decorative lighting for interiors.

Luminosity of the Magnetic Field.—Professor W. F. Barrett, of Dublin, has been making some interesting experiments to test the correctness of the discovery claimed to have been made by the late Baron von Reichenbach, viz., that a peculiar luminous effect, resembling a faint electric discharge in rarefied air, emanated from the poles of a magnet, and was rendered visible in a perfectly darkened room. Several scientific men have taken up the subject from time to time, but the only result of their labours has been to throw discredit on Reichenbach's statement. Professor Barrett is, however, of the opinion that the evidence adduced by the Baron is too weighty to be readily explained away, and resolved to make some experiments of his own to try and throw some additional light on the subject. The experiments were undertaken by a committee of the recently formed Society for Psychical Research, of which Professor Barrett formed one, and were carried out a few weeks ago at No. 14, Dean's-yard, Westminster, London, S.W. The following detailed account of what took place is abridged from a note to the *Philosophical Magazine*, communicated by Professor Barrett. He says:—One of these rooms was so arranged that it could at pleasure be made into a perfectly dark chamber, no glimmer of light being perceived even after an hour's immersion in the darkness. A powerful electro-magnet was mounted on a heavy wooden stand, and stood by itself in the centre of the room; wires led from the magnet to a commutator in another room, and thence to a large Smee battery outside. Three observers (Professor Barrett names them) were in charge of the commutator, making and breaking the current at their own pleasure, and noting down the exclamations made by the observers in the adjoining darkened room, the voice being easily heard through the intervening curtains. In the dark chamber were three other observers with Professor Barrett, together with two persons who, in a preliminary trial a day or two before, had declared they saw a luminous glare over the poles of a permanent steel magnet. These were Mr. G. A. Smith and a boy, Fred. Wells, who is an assistant in a baker's shop; both of them were entire strangers to these experiments up to the time of the preliminary trials, and disclaimed any knowledge of Reichenbach's work. For some time after entering the dark chamber nothing was seen, though during this time the electro-magnet was frequently excited. After about half an hour had elapsed, Wells, and subsequently Mr. Smith, declared they saw a faintly visible smoke in the room; being

Digitized by Google

asked where, each in turn led the Professor up to the magnetic poles as the seat of the luminosity. One pole (the north seeking pole) they said was brighter than the other. The luminosity was described as like two waving cones of light, with the apex of each cone on the magnetic poles; the breath was able to deflect but not to extinguish the glow. (In a footnote Professor Barrett likens this glow to the long ascending stream of faintly lambent aqueous vapour seen far above the flame of pure hydrogen in a well darkened room.) It was not intercepted, they said, by a black velvet cloth, nor by a deal board laid flat over the poles, but they declared it was at once obscured when these bodies were held between the eyes of the observers and the magnet, the absolute darkness being, of course, preserved continuously. When the current was cut off, both the observers simultaneously exclaimed that the light had disappeared. The current was afterwards made and broken at irregular intervals, unknown to the observers; in every case except one the latter noticed the appearance and disappearance of the glow. Professor Barrett proceeds to explain subsequent experiments that were made, all of which were successful. For ourselves, we may say that we have made similar experiments, but have only obtained negative results, whilst friends of ours have had no better fortune. However, Professor Barrett seems to have succeeded so far, and will no doubt prosecute his researches still further, for the success of which he has our best wishes.

Electric Lighting and the Board of Trade.—On Saturday last a deputation representing electric lighting companies waited upon Mr. Chamberlain at the Board of Trade. The deputation consisted of Mr. Bouverie, Mr. Arnold White, and Mr. Waterhouse representing the Edison Company; Mr. Crompton, Mr. Swan, and Mr. Morris, jun., on behalf of the Incandescent Company, and Mr. Moulton accompanied the deputation. We take the following account of the proceedings from *The Observer* of Sunday last:—"Mr. E. P. Bouverie stated the case for the deputation, and after some remarks from Mr. Moulton, Mr. Arnold White, and Mr. Crompton, Mr. Chamberlain said in reply that he regretted the tone of Mr. Bouverie's remarks. He seemed to speak with a high sense of conscious virtue, and to criticise matters which were really beside the actual circumstances of the case. He entirely concurred that it was the duty of the Department to facilitate the development of lighting by means of electricity, and much had been done by the Department to smooth away obstacles to the operations of the companies by putting them in agreement with the local authorities, and saving expense in application to Parliament. In doing this they had been to a large extent successful. Negotiations had been going on in the most friendly spirit for two months, and he was sure he would be borne out by Mr. Moulton when he said the Department had been most anxious to remove any difficulties in the way, to abandon any unreasonable claims, and to remove any obstacles of which the companies complained. But while the Board must do everything to facilitate this experiment, they were also entrusted by Parliament to protect the interests of the public, and it was not the interest of the public or of the *bonâ fide* companies that bogus companies should be established for the purpose of obtaining a *quasi* monopoly, which there was at one time great fear would be the case, for there had been applications which, if granted, would have placed the control of the further development of the system in the hands of the people who had no knowledge, no ability, and no means, and who were simply speculators with other people's money. The Board, therefore, wished to devise some means by which they might separate the bogus from the *bonâ fide* companies. They had not at present seen their way to any other means of doing this but by insisting upon some deposit of money. He would be glad if he could see his way to meet any objection which might be raised; but he would say that those conditions which seemed unreasonable to Mr. Bouverie had been accepted willingly by other companies, notably at Birmingham. What were these terms which were considered unreasonable by Mr. Bouverie? The Board had made a rule that one-half of the amount which was required to make the street works in the first schedule should be deposited, whatever proportion to the capital that might bear, but he doubted whether it would amount to more than one-sixth of the total sum which would be invested in any of these undertakings. Mr. Bouverie had said that there were no arrangements for the repayment of these sums, but in that he was mistaken, as it was distinctly provided for in the Act, and if that were not clearly expressed it might be made so after conference between the parties. He said so much as to the actual proposal, but if they could get the consent of the local authority in any case to the reduction of the amount proper, the Board of Trade would not think it at all necessary to stand out in opposition to such an agreement. But he had considerable doubt whether the terms offered of 8 per cent. by the Vestry of St. George's, Hanover-square, would be more advantageous to the company than the terms proposed by the Board, for in the former case the money was locked up until the completion of the work, whereas by the latter arrangement the money could be withdrawn in sums of not less than £1,000 during the progress of operations. A question had arisen with regard to insolvency, and it had been pointed out that the clause was almost taken *verbatim et literatim* from the Tramway Act, which had been to a considerable extent the basis upon which legislation had gone in this matter. There was also the question of transfer, which had been touched upon. Mr. Bouverie complained that the Act stipulated that no transfer of an undertaking should take place without the consent of the Board of Trade, but there had been a clear indication of the mind of Parliament that the Department were to look into every case in which transfer was proposed, and consider if there were good and sufficient reasons for objecting to it, in which case only would the Board interfere. If no good and sufficient reasons were urged against the transfer the Board would not consider it their duty to withhold their consent. As to the appointment of inspectors, there again the Board were under statutory obligations, and they had no power or funds to make appointments; but, even if they had, he did not like the notion of centralisation, of which they had already too much. A question had been raised as to the penalty of revocation which was imposed for a breach of the order. It had been urged that this was an extreme penalty, but he knew of no other expedient which would as readily ensure the compliance with the terms of the order, and it was well that the Board should be able to hold such a power over the head of the company *in terrorem* in order to secure the adequate fulfilment of the contract under which they came. In conclusion, they might say that the order in its present form had been accepted and acted upon by several companies already established. With regard to any particular case which might hereafter be brought before him, he would be glad to consider circumstances which would justify the alteration of the general scheme, for, of course, he did not say that the order which was made was to meet all the varied circumstances which might from time to time arise."

SOME ELECTROSTATIC AND MAGNETIC RELATIONS.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 511.)

6. We may see from the surface integral in (4) what to do in the case of a purely surface distribution of electricity, *i.e.*, a finite quantity of electricity upon a surface with no thickness in the layer. For, substitute for the surface charge a volume charge by endowing the layer with a small uniform thickness, t, so that if σ be the surface density, we shall have $\sigma = \rho t$. The surface-integral in (4) with the corresponding ones for Y and Z tell us that we must draw a vector of length ρ normally to the surface of the layer outward on both sides, one such vector for every unit of surface, ρ having the proper value for the portion considered. This constitutes a normal system of vectors. The volume-integral tells us that we must draw a vector tangential to the surface of length $-\nabla\rho$, one for each unit of volume of the layer, and hence we may substitute one of length $-t\nabla\rho$ for each unit of surface. The vector-potential of these two systems of vectors will be the electrostatic force at any point.

Now let Q be a point where R is required, and let its distance from a point S on the real electrified surface be r, and its distances from the corresponding points S_1 and S_2 of the outer and inner surfaces of the electric layer be r_1 and r_2, the outer surface being that next Q. Here S_2, S, and S_1 lie along the normal to the surface through S. Then, for the unit of surface surrounding S, we have the normal vectors contributing $\left(\frac{\rho}{r_1} - \frac{\rho}{r_2}\right)$ to the value of R at Q. Now let the thickness of the layer decrease indefinitely, so that S_2 and S_1 approach S; then, since $r_2 = r_1 + t\cos\epsilon$, where ϵ is the angle between r and the normal n outward, this expression becomes

$$\rho\frac{r_2 - r_1}{r_1 r_2} = \rho\frac{t\cos\epsilon}{r^2} = \frac{\sigma}{r^2}\cos\epsilon = \sigma\frac{dr^{-1}}{dn}.$$

Also, for the tangential vector, we have for the part of R contributed by the unit of surface surrounding S,

$$\frac{1}{r}(-\nabla\rho)\,t = -\frac{t}{r}\nabla\rho = -\frac{1}{r}\nabla\sigma.$$

Therefore, divide the electrified surface into unit areas. On each unit area erect a single vector of length $\frac{\sigma}{r^2}\cos\epsilon$ in the direction of the normal, and draw another of length $\frac{1}{r}\nabla\sigma$ tangential to the surface in the direction in which the surface density σ decreases fastest. The resultant of the two systems of vectors will be the electrostatic force at Q.

If the surface density be constant, we have only the normal vectors to deal with, and it might appear that the force due to an electrified *plane* surface with σ constant were always parallel to the normal, which we know to be not true, unless the surface be infinitely extended. In fact, the preceding construction applies only to a closed surface, without a bounding edge, that is to say, or to cases of unclosed surfaces in which the density decreases gradually to zero, either at the edge or before reaching the edge. We may imagine the electricity to terminate suddenly at a certain boundary. If so, we see, by first endowing the layer with thickness, that we have, in the above, neglected the edge, where we should, from every unit of area of the strip forming the edge, draw a vector of length ρ normally outward. Now, when we decrease the thickness of the layer indefinitely, the edge vectors are ultimately to be thus defined. Divide the edge (now a closed curve) into unit lengths, and from each unit length draw a vector of length $\frac{\sigma}{r}$, whose direction is perpendicular to the edge and also to the normal to the surface at its edge. It is now the resultant of the three systems, the normal, the tangential, and the edge vectors which gives the force at Q. Thus

$$\mathrm{R} = \mathrm{v.}\,\Sigma\left(\sigma\frac{dr^{-1}}{dn}\right) + \mathrm{v.}\,\Sigma\left(\frac{-\nabla\sigma}{r}\right) + \mathrm{v.}\,\Sigma\frac{\sigma}{r}. \quad . \quad . \quad (5)$$

where the first two summations are extended over the surface, and the third round its bounding edge, $\sigma\frac{dr^{-1}}{dn}$ being normal, $\frac{-\nabla\sigma}{r}$ tangential, and $\frac{\sigma}{r}$ perpendicular to the normal to the surface, and to the tangent to the edge.

Now, we also know that $\mathrm{R} = \mathrm{v.}\,\Sigma\frac{\sigma}{r^2}$ extending summation over the surface, the vectors being now drawn in the direction of r. This we may decompose into normal and tangential summations, viz.:—

$$\mathrm{v.}\,\Sigma\frac{\sigma}{r^2}(\|r) = \mathrm{v.}\,\Sigma\frac{\sigma}{r^2}\cos\epsilon\,(\|n) + \mathrm{v.}\,\Sigma\frac{\sigma}{r^2}\sin\epsilon\,(\text{tangential}).$$

Comparing which with (5), their right hand members being equal, and the first terms of the same identical, we see that

$$\mathrm{v.}\,\Sigma\frac{\sigma}{r} = \mathrm{v.}\,\Sigma\frac{\nabla\sigma}{r} + \mathrm{v.}\,\Sigma\frac{\sigma}{r^2}\sin\epsilon. \quad . \quad . \quad . \quad . \quad (6)$$

the edge summation thus being expressed in terms of surface summations of two tangential vectors, the first in the direction of greatest increase of σ, the second in the plane of r and n.

The proof of this theorem in Cartesian co-ordinates, x, y, z, is rather complex, but we may see its truth by means of Ampere's "dodge" of substituting a network of linear currents over a surface for a current round the edge. See Theorem II., p. 56, and observe that, although there the line integral is of the resolved part of a vector in the direction of the curve, and that when we substitute for it the sum of a number of other line-integrals, it being allowable to do so because the direction of rotation round the closed curves is the same for all, so that all the interior line-integrals cancel, and nothing is left but the integral round the bounding edge, yet the same method would apply exactly if the line-integral were of a vector drawn perpendicular to the edge in the plane of the surface; for if we join two points of the original closed curve by a line, thus making two circuits with a portion in common, and draw the vectors perpendicular to the curves in the plane of the surface for both circuits, outwards in each case, the vectors for the common portion are oppositely directed and of equal magnitude, and therefore annul. We see, therefore, that the edge summation $\mathrm{v.}\,\Sigma\frac{\sigma}{r}$ can be expressed by a surface summation, and that the portion of this summation for the unit of surface is nothing more than the value of $\mathrm{v.}\,\Sigma\frac{\sigma}{r}$ taken round its bounding line. We require then to know the resultant all round the line bounding the unit area enclosing any point S, of the vector of length $\frac{\sigma}{r}$ drawn perpendicular to the bounding line. Its value will depend on the tangential variation of σ in different directions from S radially, and upon the variation of $\frac{1}{r}$ about S. The first is $\frac{\nabla\sigma}{r}$, the latter $\frac{\sigma}{r^2}\sin\epsilon$, and these are the vectors that appear in equation (6), whose truth is, therefore, verified. [Vector integrals are sometimes very troublesome to manage. The above example shows the great aid to be derived from looking at the vector itself, rather than working with its components, introducing long and complex formulæ.]

If we imagine a plane surface electrified with constant density, it might be the surface of a dielectric for example, the normal vectors give a force parallel to the normal, and the edge vectors a force parallel to the plane of the surface; their resultant is the actual force. The component parallel to the plane is, of course, of great importance near the edge, making the lines of force curve outwards.

The method by which we passed from the two vectors for volume density to one normal vector for surface density and the calculation of their potential, may be compared with the process of finding the magnetic potential of a normally magnetised shell. The only difference is that we are here concerned with vectors instead of scalars. In the case of the shell we have + magnetism in one side, — in the other, of

Digitized by Google

finite amounts when the thickness is finite, and we find their combined potential at any point. Then decrease the thickness of the shell indefinitely, and increase the surface density of magnetism correspondingly, so that the magnetic moment remains constant, and find the limit to which the potential approaches. It is $\frac{\sigma}{r^2}\cos\epsilon$ per unit area. In the above, the process is the same, but the quantity operated on is a vector drawn parallel to the normal instead of a scalar. The method is also analogous to that which may be employed (p. 33 *ante*) for finding the magnetic force due to a current sheet by means of the vector-potential of the curl of the current, except that the oppositely directed vectors are tangential in that case, and the single vector is normal.

7. We may leave, however, the interpretation of the special forms which results assume for surface distributions, as it is so much easier to work with volume densities. The relations stated in sections (4) and (5) will become clearer, and a more comprehensive view of the matter will be obtained if we make the force $= \frac{e}{4\pi r^2}$ at distance r from a charge e, which is equivalent to defining the electrostatic potential $P = \Sigma\frac{\rho}{4\pi r}$.

Let P_1, R_1, P_2, R_2, P_3, R_3, P_4, . . . be quantities thus arranged. Starting with, say, P_4, let it be an arbitrary scalar; it may be volume density of electricity. Let P_3 be its potential, P_2 that of P_3, and P_1 that of P_2. The P's are therefore all scalars, and differ two degrees consecutively in length dimensions. Now between them insert R_1, R_2, R_3, . . . such that R_1 is the space variation of P_1, R_2 of P_2, and so on. Thus, the R's are all vectors, and of intermediate degrees in length dimensions.

It follows from this specification, first, that any R is the *vector*-potential of the next following R; thus, $R_1 = v.\Sigma\frac{R_2}{4\pi r}$, &c.; and, secondly, that any P is the divergence of the preceding R; and there is uniformity throughout. There is no need of additional proofs, as we have already gone through the process for two auxiliary R's, viz., R_1 below ρ and R_0 above P, in sections 5 and 4 respectively. Two consecutive P's may stand for electrostatic potential and for volume density, the intermediate R then representing the corresponding electrostatic force.

8. But we may, and with some advantage, transfer ideas from electrostatic force to the magnetic force of permanent magnets, taking the limited view of the magnetic force that it is due to magnetic "matter," as in Art. IV. "Current Energy," p. 439 *ante*. That is, we replace electricity by magnetism, electrostatic force by magnetic force, and electrostatic potential by magnetic potential; and we shall employ the definition of potential as in the last paragraph. The relations are exactly the same mathematically.

Now, besides the force due to magnetism, let there be also ordinary electric currents, and consider the resultant field, which is due to the superposition of a field consisting of closed tubes (due to current) and of another of unclosed tubes (due to magnetism). Let B be the actual magnetic force, and separate it (as done p. 439 *ante*) into B_1 and B_2, of which B_1 has no convergence, and B_2 no curl; the latter corresponding to the R's of the last paragraph. Let C_1 be the curl of B_1; it is the current density; let C_2 be the divergence of B_2; it is the density of magnetism; let A_1 be the vector-potential of C_1, and A_2 the scalar-potential of C_2. And to exhibit the relations more fully, introduce D below C, and Z above A, both vectors. Z_1 the vector-potential of B_1, Z_2 that of B_2; D_1 the curl of C_1, and D_2 the divergence of C_2.

Z	A	B	C	D
$Z_1 + Z_2$	$A_1 + A_2$	$B_1 + B_2$	$C_1 + C_2$	$D_1 + D_2$
v. v.	v. s.	v. v.	v. s.	v. v.

The quantities with the suffix 1 refer to the current system, with 2 to the magnetism. The letters v. and s. are placed to show whether they are scalar or vector. We know that Z_1, A_1, B_1, C_1, D_1 are related uniformly thus: $A_1 =$ curl Z_1, $B_1 =$ curl A_1, &c.; and also thus: $Z_1 =$ v. potential B_1, $A_1 =$ v. potential C_1, &c. Also, in the other series, $Z_2 =$ v. potential B_2, and $A_2 =$ s. potential C_2 and $B_2 =$ v. potential D_2; alternately scalar and vector; whilst a scalar in the series is derived from the preceding vector by the operation divergence, and a vector from the preceding scalar by the operation of space variation.

Observe that we may compound B_1 and B_2 and obtain B the real magnetic force. Also we may compound D_1 and D_2, since they are both vectors, forming a new vector, D; and likewise Z_1 and Z_2 (both vectors), forming a new vector, Z. And here Z, B, and D are vectors which have both curl and convergence. Also, Z is clearly the vector-potential of B, and B the vector-potential of D; because this is true of their constituents, which are in each case homogeneous—of the same nature, that is to say. But the intermediate A's and C's do not apparently admit of being combined. A_1 is truly the potential (vector) of C_1, and A_2 the potential (scalar) of C_2; but A_1 and A_2 are not homogeneous, nor are C_1 and C_2.

(TO BE CONTINUED.)

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XXI.

The employment of the two double current reversing keys in the last number seems to call for a short consideration of their practical use, and we give, accordingly, a figure, by the aid of which we desire to illustrate the action taking place in the alternate charges with positive and negative currents. The electrometer key only is drawn here, as, of course, but one current at a time passes to line, and the reader knows that both battery and electrometer keys are similarly handled. The two positions in the figure are to represent the action of the two different charges from the battery; when positive is to line the result appears as on the right hand, and as on the left when a negative charge passes. Taking the latter

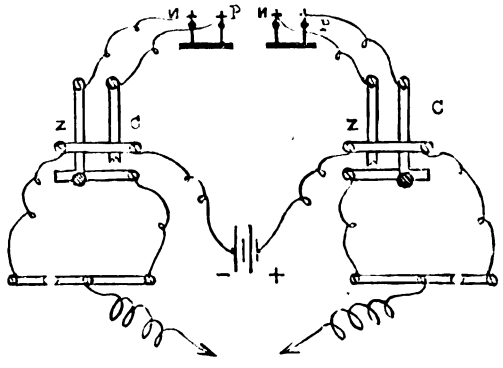

FIG. 44.—Cable Circuit, Electrometer Reversals.

charge first, on closing the circuit, the plug being in its place, the cable and both pairs of quadrants are all negatively charged, but on removing the plug (and following the plan) it is seen that a negative charge coming in from the battery, at Z, it thereby connects the pair of quadrants joined on that side to the lower bar, and this charge can now only pass by the other side C, which is in contact with the upper bar, where the charge enters; the cable is cut off from that or the C side, and so also is the pair of quadrants N in connection with it, both leaking together, and the battery connects with P. Now take the other side. C is clamped down, and the plug is in its place. The charge now as before passes to cable and all quadrants, but on lifting the plug the cable is left connected with P, the opposite pair of quadrants to that previously charged, and the bar remains in connection with the other pair N. We have been able to illustrate the alternate separation of the key pieces from the lower bar, but cannot very well show the cutting off from the upper bar, so the reader must remember that the depression of a key piece severs the connection on

Digitized by Google

that side between the upper and lower bars. The object obtained by these two double current keys might also have been effected by means of a plug commutator, a four-way piece; an example of its use appears in several figures. We have not at present any fresh test to suggest, but shall now present two modes of taking what are called final tests. They are for insulation resistance, and on the principle of that first explained, in which this quality is measured by deflection whilst the battery charge is continuous. When any section of cable is completed it is customary to take special insulation tests for periods of from thirty minutes to an hour. The length of time generally depends on the length of section, over thirty knots being one that requires the longer of the two operations. One of these will be taken shortly after completion of the section, and another when the same length is to be shipped. In both cases the cable is well under water, the end also being generally sealed—that is, completely covered with gutta percha, so as to be protected from the air. Of two ways of making these tests, in both of which positive and negative currents are employed, one consists in applying the currents alternately for half an hour, reversing every minute; in the other one current is used for thirty or sixty minutes, a reading being taken every minute or half minute, and after an interval of two or three hours, during which the cable is put to earth to free it entirely of its charge, the same operation is performed with the opposite current. Of the two methods the first is the more severe, as reversals whilst two or three hundred cells are being employed will prove more searching than one current continuously applied. The tests, however, are taken with the assumption that the cable is perfect, and the latter of the two is preferable in the fact that it furnishes data for pronouncing on the goodness of the section. We will commence with the forms of two, calling it a "half-hour minute reversal test."

The operator must first assure himself that the cable is properly under water, and the further end sealed, or, if not sealed, well insulated and carefully protected against any interference. As regards the choice of current to commence with, some prefer *negative*, and others *positive*. Let us commence with the former. In the case of a good, that is a perfect cable, the point is of much less importance than if a fault were present. We suppose the galvanometer scale to be of the ordinary length and type, with zero at the centre, and the shunt must be chosen with a view to the production of a deflection as large as possible, and as the readings are all to be taken after one minute's charge, the operator will arrange the circuit so that the spot may be as near as may be convenient to the end of the scale when the minute expires, convenience referring to the desirability of watching the progress of the deflection during the interval. As we have in an early number fully explained the course of the ordinary galvanometer insulation test, there is but little detail to be considered; a general direction to be very careful and exact is, however, imperative. A learner, as such, would never be directed to take a final test; but there must be a first time, and to any one thus commencing we particularly address our cautions. One point is specially worth noting. It will be seen at once that, as the readings are taken once every minute and each successive deflection is the result of an opposite charge to that of the preceding one, some portion of time, however limited, must be occupied in the act of reversal. If, for example, the negative charge were applied at, say, eleven o'clock exactly, and the deflection read at eleven hours one minute, on then reversing, however quickly, the positive charge would not have endured sixty seconds when its reading was taken at eleven hours two minutes; at the very least two or three seconds must have been spent in reversing the battery key and commutator, especially as the galvanometer must be short circuited between the two charges. The course to be followed then will be to charge, say, with zinc at a full minute, as at eleven, the short circuit plug being of course in its place; this will be removed after fifteen or twenty seconds, and the spot as arranged according to the suggestion above will appear at the end of scale, say at thirty seconds. This will be watched till close on the end of the minute, that is two or three seconds before it expires, when the short circuit plug must be promptly inserted and the key reversed; of course the charging side must be released first and the other side instantly put down. The readings on a scale of the ordinary type will be really that of the fifty-eighth second, but where the divisions are so small the result is sufficiently correct. The reversal must be so timed as to cause the charge to act at the exact minute. It is impossible to have exactly a sixty seconds' reading unless we should commence each succeeding minute a second or two later. The operator must be wary and collected. The positive and negative readings may either be taken on different sides of zero, or by reversing the commutator plugs both may be read off on one side. It is better, however, not to shift the plug, for a reason given in a former number, and also to prevent even the minute loss of time occupied in the change. The deflection will in the case of a perfect cable be the same, or nearly so, for both currents. The cable should be entirely free of charge before commencing, or as nearly as it can ever be; at the end of the test it must be put to earth again, and so remain.

As regards the test for 30 minutes each with alternate currents there is nothing to be added to our instructions for the ordinary test. The cable is first tested with one current for the time fixed, readings being taken every minute, and, after being put to earth for an hour or two, the other current is similarly observed. It is not customary to read at less intervals than one minute when using the ordinary sized scale, but an arrangement is in use at certain establishments by which a deflection may be obtained at every 30th second. Moreover, there are features in this test which render it the best and most conclusive of all final tests. It consists of a long and wide scale, graduated like the smaller one, but whose divisions are at least $\frac{1}{8}$in. apart. A covered lamp is provided with a tube and sliding lens for adjusting the focus, and a fine wire is stretched perpendicularly across the end, dividing the light into two hemispherical portions. The lamp is slightly tilted, and is so placed with relation to the galvanometer that the rays of light slope upward to the mirror, and are thence again reflected upwards to the scale, which is fixed on a wall behind the lamp. The focus is adjusted so that the light falls on the scale, and is there represented by a glowing circle varying in size according to the adjustment, and perpendicularly divided by a fine black line, which latter clearly marks each division and half-division as it passes on. The divisions are all counted as whole numbers, but when the spot travels slowly the fine centre line stands easily between any two divisions, and at this point the reading is counted as a half-division. This is decidedly the best of all arrangements for taking a long insulation test, and much greater accuracy is possible than with a small scale and spot. The test, briefly, is as follows:—The cable is charged at some definite time, the full hour, or five, ten, &c., minutes past. The readings are first taken, say, with zinc, every thirty seconds; the first two or three readings are not so easy to catch, as the spot is then travelling fast, and the deflections must be carefully estimated that the division may be marked exactly at the thirtieth second. The spot, however, travels slowly after these readings, and nothing more than watchfulness is required till the fifty-ninth minute, when the operator is to look out for the next thing to be done, which is this:—What are called "earth readings" are to be taken for five minutes, and then five minutes' observation with the opposite current (to that in the cable) before finally discharging. At about the fiftieth section after the fifty-ninth minute the deflection may be noted, and instantly the galvanometer must be short circuited, and exactly at the sixtieth second (and sixtieth minute) the charging battery key released. This puts the cable to earth; then, as the charge going out of it acts on the mirror magnet in an opposite direction to one entering it, the galvanometer commutator (or reversing key, if used) must be reversed, that the spot may travel in the same direction as before. The galvanometer short circuit is then removed, and the spot appears travelling down, but very quickly at first, and the deflections are to be read at every minute. Just before the fifth minute reading the galva-

Digitized by Google

nometer is to be short-circuited again (the deflection, however, being recorded as it then appears), and at the exact fifth minute the other. In this case the positive current is put on, and readings are to be taken for five minutes, and the test is finished (that is, the first half of it). The battery is not, however, taken off for about twenty minutes more, an interval allowed to enable the positive current to neutralise the negative, which has been saturating the cable for so long a time. After this period the battery key is released, and the cable is then put to earth. Two hours later the same operation is repeated, but with the reverse current; the test is exactly the same in all respects.

Our space is at present very limited, and we have to turn our attention to some of the duties involved in the shipping and submersion of cables, and shall therefore conclude this paper with an illustration of the signalling key and switch generally used at shore stations for communication with the ship and with the distant station. The mirror key in Fig. 45 is really the same thing as the ordinary testing key, but in practice is made to suit the convenience of the signalling operator. Every electrician ought to be able to read and send signals on the mirror. The dotted lines represent portions not seen in the actual key and switch; they are underneath, and so out of the way—one terminal goes to earth, and the other to line, that is to K in the switch. The handle of this

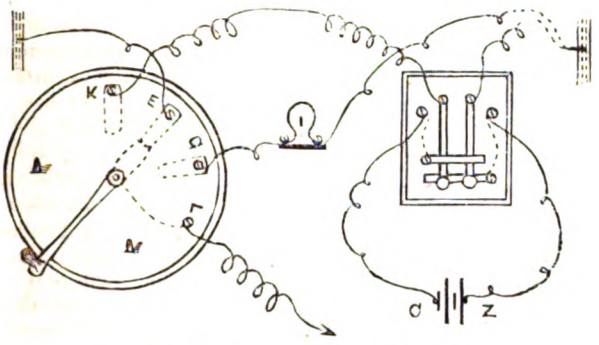

FIG. 45.—Signalling Key and Switch.

latter can be turned on to G when signals come in from the ship and are recorded on the mirror and thus read off; when the operator wants to send a signal or message the handle is turned on to K, and the signals go direct to the cable (by L always joined to the handle centre) without passing through the mirror, which would be useless; when turned on to E the cable is put to earth. The two little stops in the switch are merely pins or rests to keep the handle firm, either for receiving or sending, as when it rests against either the end is pressed against the connection plate at G or K. The earth terminal E is placed between G and K so as to put the cable to earth between receiving and sending. The pieces G, E, K are springs for safer contact by pressure with the handle terminal.

OPPOSITION TO ELECTRIC LIGHTING.—A meeting of delegates from the vestries of Kensington and St. Martin-in-the-Fields and the district boards of Holborn, St. Giles, and Westminster was held on Friday, April 20, at the offices of the Westminster District Board, 25, Great Smith-street, S.W., Mr. T. J. White (Westminster) in the chair, to consider the course to be adopted with reference to a communication received from the Board of Trade, forwarding copy of model provisional order proposed to be granted to the various electric lighting companies. The following resolutions were carried: "That this meeting is of opinion that it is undesirable for the Board of Trade to force electric lighting upon any district under present circumstances in opposition to the desire of the local authority." "That this meeting is of opinion that an extension of time should be granted by the Board of Trade, so as to allow full opportunity to the local authorities for considering the model clauses of the provisional order relative to electricity issued by the Board, and to give their replies thereto."

THE INSTITUTION OF CIVIL ENGINEERS.

The fifth of the series of six lectures on the Applications of Electricity was delivered on Thursday evening, the 19th of April, 1883, by Professor F. A. Abel, C.B., F.R.S., Hon. M. Inst. C.E. The subject was "Electricity Applied to Explosive Purposes." The following is an abstract of the lecture:—

In introducing the subject the lecturer indicated the principal advantages which it had been early observed would result from a certain mode of firing explosive charges by electric current instead of by the ordinary fuzes, the best of which had inherent defects, greatly limiting their use for any but the simplest operations. He traced the history and development of electric firing from the crude experiments of Benjamin Franklin, about the year 1751, through the various stages in which frictional electricity, volta-induction apparatus, and magneto-electric machines had supplied the means of generating the current, the tendency of late years being to revert to a modified form of voltaic battery for one class of work, and to employ dynamo-electric machines for another class. The history and development of the low-tension, or wire-fuse, and of the various fuzes employed with electric currents of high-tension, were also discussed, and their relative advantages, defects and performances were described.

The only sources of electricity which at present thoroughly fulfilled the conditions essential in the exploding agent for submarine mines were constant voltaic batteries. They were simple of construction, comparatively inexpensive, required but little skill or labour in their production and repair, and very little attention to keep them in constant good working-order for long periods, and their action might be made quite independent of any operation to be performed at the last moment.

When first arrangements were devised for the application of electricity in the naval service to the firing of guns and so-called outrigger-charges, the voltaic pile recommended itself for its simplicity, the readiness with which it could be put together and kept in order by sailors, and the considerable power presented and maintained by it for a number of hours. Different forms of pile were devised at Woolwich for boat and ship use, the latter being of sufficient power to fire heavy broadsides by branch circuits, and to continue in a serviceable condition for twenty-four hours, when they could be replaced by fresh batteries, which had in the meantime been cleaned and built up by sailors.

The Daniell and sand batteries first used in conjunction with the high tension fuse for submarine mining service were speedily replaced by a modification of the battery known as Walker's, which was after some time converted into a modified form of the Leclanché battery.

The importance of being able to ascertain by tests that the circuits leading to a mine, as well as the fuses introduced into that circuit, were in proper order, very soon became manifest; and many instances were on record in the earlier days of submarine mining of the disappointing results attending the accidental disturbance of electric-firing arrangements, when proper means had not been known or provided for ascertaining whether the circuit was complete, or for localising any defect when discovered.

The testing of the Abel fuze, in which the bridge, or igniting and conducting composition, was a mixture of the copper phosphide and sulphide with potassium chlorate, was easy of accomplishment (by means of feeble currents of high tension), in proportion as the sulphide of copper predominated over the phosphide. Even the most sensitive might be thus tested with safety; but when the necessity for repeated testing, or even for the passing of a signal through the fuze, arose, as in a permanent system of submarine mines, the case was different, this fuze being susceptible of considerable alterations in conductivity on being frequently submitted to even very feeble test-currents, and its accidental ignition, by such comparatively powerful test or signal currents as might have to be employed, became so far possible as to create an uncertainty which was most undesirable.

Hence, and also because the priming in these fuses was liable to some chemical change detrimental to its sensitiveness, unless thoroughly protected from access of moisture, another form of high-tension fuse, specially adapted for submarine mining service, was devised at Woolwich. This, though much less sensitive than the original Abel fuse, was sufficiently so for service requirements, while it presented great superiority over the latter in stability and uniformity of electric resistance; and, though not altogether unaffected by the long-continued transmission of test currents through them, the efficiency of the fuse was not affected thereby.

Although high tension fuses presented decided advantages in point of convenience and efficiency over the earlier form of platinum wire fuse, the requirements which arose, in elaborating thoroughly efficient permanent systems of defence by submarine mines, and the demand for a battery for use in ships which would remain practically constant for long periods, caused a very care-

Digitized by Google

ful consideration of the relative advantages of the high and low tension systems of firing to result in favour of the employment of wire fuses for these services. In addition to the disadvantages pointed out there was an element of uncertainty, or possible danger, in the employment of high tension fuses, which, though fully eliminated by the adoption of voltaic batteries, in place of generators of high tension electricity, might still occasionally constitute a source of danger, namely, the possibility of high tension fuses being accidentally exploded by currents induced in cables, with which they were connected, during the occurrence of thunderstorms, or of less violent atmospheric electrical disturbances

Experiment, and the results obtained in military service operations, had demonstrated that if insulated wires, immersed in water, buried in the earth, or even extended on the ground, were in sufficient proximity to one onother, each cable being in circuit with a high-tension fuze and the earth, the explosion of any of the fuses by a charge from a Leyden jar, or from a dynamo-electric machine of considerable power, might be attended by the simultaneous ignition of fuses attached to adjacent cables, which were not connected with the source of electricity, but which become sufficiently charged by the inductive action of the transmitted current. It therefore appeared very possible that insulated cables extending to land or submarine mines, in which high tension fuses were enclosed, might become charged inductively during violent atmospheric electrical disturbances to such an extent as to lead to the accidental explosion of mines with which they were connected. In a report by Von Ebner on the defence of Venice, Pola, and Lissa, by submarine mines, in 1866, he refers to the accidental explosion of one of a group of sixteen mines during a heavy thunderstorm, as well as to the explosion of some mines, by the direct charging of the cables, through the firing station having been struck by lightning. Two instances of the accidental explosion of tension fuses by the direct charging of overhead wires during lightning discharges occurred in 1873 at Woolwich.

Subsequently an electric cable was laid out at Woolwich along the river bank below low water mark, and a tension fuze was attached to one extremity, the other being buried. About eleven months afterwards the fuse was exploded by a charge induced in the conductor during a very heavy thunderstorm.

In consequence of such difficulties as these experienced in the special application of the high tension fuses to submarine purposes, the production of comparatively sensitive low tension fuses, of much greater uniformity of resistance than those employed in former years, was made the subject of an elaborate experimental investigation by the lecturer. Different samples of comparatively thin wires, made from commercial platinum, showed very great variations in electrical conductivity. Very considerable differences in the amount of forging to which the metal, in the form of sponge, had been subjected, did not importantly affect either its specific gravity or its conductivity, and the fused metal had only a very slightly higher degree of conductivity than the same metal forged from the sponge. The conductivity of very fine wires could therefore be but slightly affected by physical differences in the metal, and the considerable differences in conductivity observed in different samples of platinum were therefore chiefly ascribable to variations in the degree of its purity. It appeared likely that definite alloys might furnish more uniform results than commercial platinum; experiments were therefore made with fine wires of German silver, and of the alloy of 66 of silver with 33 of platinum employed by Matthiessen for the reproduction of B. A. standards of electrical resistance. Both were greatly superior to ordinary platinum in regard to the resistance opposed to the passage of a current; German silver was in its turn superior to the platinum silver alloy; although the difference was only trifling in the small lengths of fine wire used in a fuse (0·25 inch), while the comparatively ready fusibility of the platinum silver wire contributed, with other physical peculiarities of the two alloys, to reduce the fine German silver wire to about a level with it. Moreover, the latter did not resist the tendency to corrosive action exhibited by gunpowder, and other more readily explosive agents, which had to be placed in close contact with the wire bridge in the construction of a fuze, while the platinum silver was found to remain unaltered under corresponding conditions. Experiments having also been made with alloys of platinum with definite proportions of iridium, the metal with which it is chiefly associated, very fine wires of an alloy containing 10 per cent. of iridium were eventually selected as decidedly the best materials for the production of wire fuzes of comparatively high resistance and uniformity, this alloy being found decidedly superior in the latter respect, as well as in point of strength (and therefore of managableness in the state of very fine wire, 0·001in. in diameter), to the platinum silver wire. The fuzes now used in military and submarine services were made with bridges of iridio-platinum wire, containing 10 per cent. of the first named metal.

The electrical gun tubes in the navy were fired by means of a specially arranged Leclanché battery, and branch circuits worked to the different guns; in broadside firing, it was important that the wire bridge of any one of the gun-tubes which was first fired should be instantaneously fused on the passage of the current, so as to cut this branch out of circuit; in this respect the comparatively fusible platinum silver alloy appeared to present an advantage, hence the naval electrical fuses were made with bridges of that alloy. Uniformity of electrical resistance had become a matter of such high importance in the delicate arrangements connected with the system of submarine mines, as now perfected, that the very greatest care was bestowed upon the manufacture of service electric fuses and detonators, which were in fact made, in all their details, with almost the precision bestowed upon delicate scientific instruments, and the successful production of which involved an attention to minutiæ which would surprise a superficial observer.

One of the earliest applications of electricity to the explosion of gunpowder was the firing of guns upon proof at Woolwich by means of a Grove battery and a gun tube, which was fired by a platinum wire bridge, a shunt arrangement being used for directing the current successively into the distinct circuits connected with the guns to be proved. When the high-tension fuze had been devised, gun tubes were made to which it was applied, and an exploder was arranged by Wheatstone, having a large number of shunts, so that as many as twenty-four guns might be brought into connection with the instrument, and successively fired by the depression of separate keys connected with each.

The firing of cannon, as time signals, was an ancient practice in garrison towns, but the regulation of the time of firing the gun, by electrical agency from a distance, appears first to have been accomplished in Edinburgh, where, since 1861, the time gun had been fired by a mechanical arrangement, actuated by a clock, the time of which is controlled electrically by the mean time clock at the Royal Observatory on Calton Hill.

Shortly after the establishment of the Edinburgh time-gun, others were introduced at Newcastle, Sunderland, Shields, Glasgow, and Greenock. The firing of the gun was arranged for in various ways; in some instances it was effected either direct from the observatory at Edinburgh, or from shorter distances, by means of Wheatstone's magneto-electric exploders. At present there were time-guns at West Hartlepool, Swansea, Tynemouth, Kendal, and Aldershot, which were fired electrically, either by currents direct from London, or by local batteries, which were thrown into circuit at the right moment by means of relays, controlled from St. Martin's-le-Grand.

About thirteen years ago, the electrical firing of guns, especially for broadsides, was first introduced into the Navy, with the employment of the Abel high-tension gun-tube and voltaic piles. The gun tubes then used were manufactured simply for the proof of cannon and for experimental artillery operations, and were of very simple and cheap construction. Experience proved them to be unfitted to withstand exposure to the very various climatic influences which they had to encounter in Her Majesty's ships, and in store in different parts of the world. The low-tension gun tubes, having a bridge of very fine platinum-silver wire, surrounded by readily-ignitable priming composition, were therefore adopted as much more suitable for our naval requirements.

The arrangements for broadsides or independent firing, and also for the firing of guns in turret ships, had been very carefully and successfully elaborated in every detail, including the provision of a so-called drill or dummy electrical gun tube, which was used for practice, and refitted by well-instructed sailors. The firing keys and all other arrangements connected with electrical gun firing were specially designed to ensure safety and efficiency at the right moment.

The electric detonators for firing outrigger torpedoes, or for other operations to be performed from open boats, corresponded, so far as the bridge was concerned, with the naval electric gun tubes, and were fired with a specially-fitted Leclanché battery. These electrical appliances were now distributed throughout the Navy, and the men were kept, by instruction and periodical practice, well versed in their use.

The application of electricity to the explosion of submarine mines, for purposes of defence and attack, received some attention from the Russians during the Crimean War under the direction of Jacobi; thus a torpedo, arranged to be exploded electrically when coming into collision with a vessel, was discovered at Yeni-Kale, during the Kertsch expedition in 1855. Some arrangements were made by the British, at the conclusion of the war, to apply electricity to the explosion of large powder charges for the removal of sunken ships, &c.,

Digitized by Google

in Sebastopol and Cronstadt Harbours. In 1859, a system of submarine mines, to be fired through the agency of electricity by operators on shore, was arranged by Von Ebner for the defence of Venice, which, however, never came into practical operation. Early in 1860, Henley's large magneto-electric machine, with a supply of Abel fuzes, and stout india-rubber bags, with fittings to resist water pressure, were despatched to China, for use in the Peiho River, but no application appeared to have been made of them. The subject of the utilisation of electricity for purposes of defence, however, did not receive systematic investigation in England or other countries until some years afterwards, when the great importance of submarine mines as engines of war was demonstrated by the number of ships destroyed and injured during the war in America.

The application of electricity to the explosion of submarine mines was very limited during that war, but arrangements for its extensive employment were far advanced in the hands of both the Federals and Confederates at the close of the war; men of very high qualifications, such as Captain Maury, Mr. N. J. Holmes, and Captain McEvoy having worked arduously and successfully at the subject.

The explosion of submerged powder charges by mechanical contrivances either of self-acting nature or to be set into action at desired periods was accomplished as far back as 1583 during the siege of Antwerp by the Duke of Parma, and from that period to 1854 mechanical devices of more or less ingenious and practical character had been from time to time applied to some small extent in different countries for the explosion of torpedoes. The Russians were the first to apply self-acting mechanical torpedoes with any prospect of success, and had the machines used for the defence of the Baltic been of larger size (they only contained 8 or 9lb. of gunpowder), their presence would probably have proved very disastrous to some of the English ships which came into collision with and exploded them. Various mechanical devices for effecting the explosion of torpedoes by their collision with a ship were employed by the Americans, a few of which proved very effective. But although in point of simplicity and cost, a system of defence by means of mechanical torpedoes possessed decided advantages over any extensive arrangements for exploding submarine mines by electric agency, their employment was attended by such considerable risk of accident to those at whose hands they received application that, under many circumstances which were likely to occur, they became almost as great a source of danger to friend as to foe.

The most important advantages secured by the application of electricity as an exploding agent of submarine mines were as follow:—They might be placed in position with absolute safety to the operators, and rendered active or passive at any moment from the shore; the waters which they were employed to defend were therefore never closed to friendly vessels until immediately before the approach of an enemy; they could be fixed at any depth beneath the surface (while mechanical torpedoes must be situated directly or nearly in the path of a passing ship), and they might be removed with as much safety as attended their application.

There were two distinct systems of applying electricity to the explosion of submarine mines. The most simple was that in which the explosion was made dependent upon the completion of the electric circuit by operators stationed at one or more posts of observation on shore; such a system depended, however, for efficiency, on the experience, harmonious action, and constant vigilance of the operators at the exploding—and observing—stations, and was, moreover, entirely useless at night, and in any but clear weather.

The other, which might also be used in conjunction with the foregoing, was that of self-acting mines, exploded either by collision with the ship, whereby circuit was completed through the enclosed fuse, or by the vessel striking a circuit closer, whereupon either the mine, moored at some depth beneath, was at once fired, or the necessary signal was given to the operator on shore.

Continental nations had followed in our footsteps, in providing themselves with equipments for defensive purposes by submarine mines, and the Danes, Swedes, and Norwegians, had pursued the subject of submarine mines with special activity and success.

In the United States the subject of the utilisation of electricity as an exploding agent for war purposes was being actively pursued, and important improvements in exploding instruments, electric fuses, and other appliances had been made by Smith, Farmer, Hill, Striedinger, and others already mentioned, while no individual had contributed more importantly to the development of the service of submarine explosions than General Abbot, of the United States Engineers.

Illustrations of actual results capable of being produced in warfare by submarine operations had hitherto been very few, but of the moral effects of submarine mines there had already been abundant illustrations. In the war carried on for six years by the Empire of Brazil and the Republic of Uruguay and the Argentine Republic of Paraguay the latter managed by means of submarine mines to keep at bay for the whole period the Brazilian fleet of fifteen ironclads and sixty other men-of-war. In the Russo-Turkish war submarine mines and torpedoes were a source of continued apprehension, and the French naval superiority was paralysed during the Franco-German war by the existence, or reputed existence, of mines in the Elbe.

The application of electricity to the explosion of military mines and to the demolition of works and buildings had been of great importance in recent wars in expediting and facilitating the work of the military engineer. The rapidity with which guns, carriages, &c., were disabled and destroyed by a small party of men who landed after the silencing of the forts at Alexandria illustrated the advantages of electrical exploding arrangements, combined with the great facility afforded for rapid operations by the power possessed of developing the most violent action of gun-cotton, dynamite, &c., through the agency of a detonator.

The application of electricity to the explosion of mines for land-defences during active war was not an easy operation, inasmuch as not only the preparation of the mines, but also the concealment of electric cables and all appliances from the enemy, entailed great difficulties, unless the necessary arrangements could have been made in ample time to prevent a knowledge of them reaching the enemy.

But few words need be said to recall to the minds of civil engineers the facilities which the employment of electricity to explosive purposes afforded for expediting the carrying out of many kinds of works in which they were immediately interested. Electrical blasting, especially in combination with rock-boring machines, had revolutionised the operation of tunnelling and driving of galleries; and, although in ordinary mining and quarrying operations the additional cost involved in the employment of fuses, conductors, and the exploding machine, was not unfrequently a serious consideration, there were, even in those directions, many occasions when the power of firing a number of shots simultaneously was of great importance. There was little doubt, moreover, that accidents in mining and quarrying would be considerably reduced in number if electrical blasting were more frequently employed.

The conveniences presented by electric firing arrangements, under special circumstances, were interestingly illustrated by a novel proceeding at the launch of a large screw steamer at Kinghorn, in Scotland, which was recently accomplished by placing small charges of dynamite in the wedge-blocks along the sides of the keel, and exploding them in pairs, hydraulic power being applied at the moment that the last wedge was shot away.

In the deepening of harbours and rivers, and in the removal of natural or artificial submerged obstructions, the advantages of electric firing were so obvious that extended reference to them was unnecessary.

A substitute for electrical firing, which had been applied with success to the practically simultaneous firing of several charges, consisted of a simple modification of the Bickford fuze, which, instead of burning slowly, flashed rapidly into flame throughout its length, and hence had received the name of instantaneous fuze, or lightning fuze. The fuze burned at the rate of about 100 feet per second; it had the general appearance of the ordinary mining fuze, but was distinguished from the latter by a coloured external coating. Numerous lengths of this fuze were readily coupled up together, so as to form branches leading to different shot-holes, which might be ignited together, so as to fire the holes almost simultaneously. In the Navy this fuze was used as a means of firing small gun-cotton charges to be thrown by hand into boats when these engaged each other, the fuze being fired from the attacking boat by means of a small pistol, into the barrel of which the extremity was inserted.

OBITUARY NOTICE.—We have to record the death of Mr. William Cherry, the foreman of the mechanical, the fitting, and the erecting departments of the well-known firm of Messrs. Johnson and Phillips, telegraph engineers, Charlton, S.E. The burial took place on Wednesday at the quiet little Brockley Cemetery, and besides the chief mourners there were gathered together at the grave the heads of the firm, all the officials and many of the leading hands. It was the boast of the old gentleman that he had always been at his duties never later than six o'clock in the morning during the whole time he had held the position of foreman in the works, and it might literally be said that he actually died in harness, for up to the day before his death he was at his work as usual. Although not prominently known in the electrical world, Mr. Cherry was intimately associated with telegraphy. It was under his supervision that some of the first, now celebrated, lamps invented and patented by Mr. Brockie were made, and at the time of his death we are informed that heavy cable machinery, destined for the new Postal telegraph ship, was being carried out under his care at the works in Charlton.

ANSWERS TO CORRESPONDENTS.

C. E. M.—*You had better read the recent Cantor Lectures by Professor S. Thompson. The lectures have been reprinted by the Society of Arts in pamphlet form, and cost one shilling. To your second question, concerning Rhumkorff's coils, yes.*

H. N. L.—*We do not think the South Kensington certificate worth anything, nor do we think a cart load of certificates would gain an appointment unless they were backed by practical experience. If you have made up your mind to enter into electric light work, or telegraphy, or telephony, we should advise you at the same time to make up your mind for hard work. Take any work that may be obtainable in the branch you select. If electric lighting, use your spare time to get theoretical knowledge of the subject and a practical knowledge of mechanical engineering. The best electric light engineers are those whose knowledge is not confined to electrical matters, but includes a good knowledge of practical and theoretical mechanics.*

MR. CHAMBERLAIN AND THE ELECTRIC LIGHTING COMPANIES.

The deputation which waited on the President of the Board of Trade on Saturday last did not, we fear, come away particularly satisfied with their interview. It is somewhat difficult to make out what they went for, the reports of the proceedings, especially in respect to the speeches of the interviewers, being meagre and obscure. Only from Mr. Chamberlain's reply can we make out, with any degree of certainty, what the deputation wished him to concede, and what it was upon which he dismissed them unsatisfied. Judging, however, from information derived from newspaper reports, we are inclined to agree with the official President, and not with the representatives of the public companies. We may be wrong in this; but, if so, the deputation have themselves to blame in not making their grievances more widely known, so that they might have been fully discussed on their merits.

We have so often taken exception to the whole tenour of the Bill of which Mr. Chamberlain was the reputed father, and have so freely criticised his interpretation of it, that we shall not be suspected of partiality either for him or his scheme; but in the present instance he appears to have had both justice and common sense on his side, and we can take little exception to the answer he gave Mr. Bouverie and his following. The Electric Lighting Act stipulates, in respect to the contract between any electric lighting undertakers and the local authorities, that the former shall deposit, before taking up the streetways, a sum equal to half of the estimated cost of the work to be done—that is to say, work coming strictly under the head of street works. The proportion this would represent of the whole amount expended in laying down wires and installing the electric light must obviously be small; Mr. Chamberlain estimated it at only one-sixth of the total capital required. Yet the deputation strongly object to this arrangement, on the, as it seems to us, very inadequate ground that it was contrary to public policy, and, if insisted on, would prevent the public embarking their money in these undertakings, thus discouraging the improved illumination, which is everywhere admitted to be desirable.

Probably some stronger argument is capable of being framed against the objectionable clause; but, substantially, this was the one put forward on Saturday. That several highly respectable representatives of electric lighting enterprise joined in the protest, lame though it was, is not surprising. Their progress is being hampered and hindered at every step by vexatious opposition, or passive indifference, on the part of the local vestries, whose name is legion and whose powers are infinite. Anything likely to curtail those powers, or lessen their capacity for obstruction, would naturally be welcome to all undertakers alike, and as any rope is good enough to hang a dog with, the half deposit rule, under Schedule A, was as good as any other wherewith to strangle the local boards. On this point, however, Mr. Chamberlain stood up as a champion of local rights, and their assailants came away discomfited. Mr. Chamberlain is reported to have commenced by saying he regretted the tone of Mr. Bouverie's remarks. Probably by this time his feeling is shared by all the deputation, though the Minister's own tone was far from unexceptionable.

Leading off with this deprecatory observation, the President of the Board of Trade proceeded to exemplify the sort of tone a minister may adopt when addressing a deputation. "Mr. Bouverie seemed to speak," so Mr. Chamberlain's words are reported, "with a feeling of conscious virtue, and to criticise matters which were really beside the actual circumstances of the case." Now, it is unwise at all times not to stick to the point; but why a man should not speak with conscious virtue does not so plainly appear. Either the Minister of the trade of this country has ceased to believe in virtue, which does not speak well for the moral atmosphere of the department over which he has control, or else he did not believe in Mr. Bouverie's virtue—an expression of opinion

Digitized by Google

which may be correct "tone" at the office of the Board of Trade, but which is universally eschewed at the respectable clubs in its immediate neighbourhood. Probably this tradesmanlike view of virtue in general, and of Mr. Bouverie's in particular, is peculiar to the present chief of the Board of Trade, who may, for aught we know, be smarting under the immediate sense of his responsibilities in calling into being and encouraging with inconsiderate haste a host of undertakings which have finally proved themselves to be deficient in the one only virtue worth having—namely, funds. On the other hand, with a catastrophe such as that which overtook a large undertaking company the previous day, and several others of the same kind impending, any man may be excused speaking with conscious virtue, if he has any; and it is not expedient to discourage the expression of it.

But, if the spokesman of the deputation meant to attribute similar virtue—that is to say, solvency—to all the would-be applicants for electric lighting contracts, he was clearly in error, and it was here he betrayed the weak side of his case. Mr. Chamberlain could retort that there were a lot of bogus companies in the field, whose object was to spend other people's money—he might have said to appropriate it—and that it was not in the interests of electric lighting in the long run that these ignorant and unscrupulous speculators should be allowed to discredit the business by failing to perform their obligations. We are bound to endorse this view of the case; and we cannot help feeling some surprise that a condition already imposed on the tramway companies, and unexceptionable on grounds of prudence and fair treatment of the local authorities, should be objected to by any company with money and science at its back. Local burdens are sufficiently oppressive already without their being saddled with the consequences of experimental financing.

SUPPLEMENT No. III.

This Supplement is, in reality, a Supplement to No. II., and is intended to be used in conjunction with it. The figures are readily obtained from the former Supplement, but it has been thought more convenient to have some such tabular extension as we now issue. The figures in Supplement No. II., as we have before stated, were taken because they were such as had been tested by considerable use in actual practice, and err upon the side of safety. We are now having a series of independent tests made to corroborate Professor Forbes's formulæ, and hope in due course to construct tables of a more scientific character founded upon these formulæ.

FIRE AT THE CANADIAN PARLIAMENT HOUSE.—Telegrams to the daily Press from New York have attributed the origin of the fire which recently occurred in the Parliament House at Quebec to the electric light installation there. In the absence of any trustworthy information as to the why and wherefore of the fire we may say this, that if it has been occasioned by the short-circuiting of wires, or by the use of currents too high for the wires which carried them, or by any similar mishap, then it must be put down to the bad workmanship of those who are responsible for the installation. However, it may turn out, after all, not to have been caused in this way, and not to be due to the electric light and its belongings. Of this we are positively certain, viz., that, where fires are started by electric light wires or fittings, gross carelessness and bad workmanship are the primary causes.

CORRESPONDENCE.

EARTHQUAKES AND THEIR ORIGIN.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Shortly after the disastrous earthquake at Chios in 1881, I had occasion to address a letter to you on the subject, containing some observations made during a series of years in this island, where strong shocks are periodical and slight ones very frequent.

I then pointed out to your readers that on one occasion my astatic galvanometer had been rendered temporarily useless for testing that day, owing to the needles having been strongly influenced by an evolution of the earth's magnetism both previous to and subsequent to a very smart shock. The instrument, however, returned to its normal state in a few hours' time, and continued so.

Unfortunately then my testing room was too far away from the town to enable me to rush there at any hour on the recurrence of a strong shock to verify the idea that earthquakes are solely attributable to a disarrangement of the earth's magnetic polarity.

Since last autumn, however, the cables' ends have been brought into the office, and I anxiously awaited an opportunity for verifying and confirming my previous observations. Of course, no such opportunity offered itself, and, despite a very severe winter, a continuance of hurricanes, and other violent atmospherical disturbances, we enjoyed (as I pointed out to you in my note of February 24) an especial immunity from earthquake shocks.

The generally-accepted theory out here, that unusual heat or cold, the filtration of rain through the earth intermixing with the internal gases, &c., cause earthquakes was entirely at fault, for, despite deluges of rain and weather unexampled for years, the earth remained perfectly quiescent. When the eruption of Etna the other day became known everybody at once felt relieved, fancying that the vent at the volcano would certainly prevent any similar subterranean explosion in our vicinity. This "theory," however, exploded, as I propose to show.

On Monday last, April 2nd, the wind, which all day had been due south, with atmosphere hazy, suddenly changed to north-east; in fact, for a short time and until the latter predominated, the wind was actually south north-east.

The following morning I had to test two sections—Zante-Corfu and Zante-Canea. The former cable gave its normal results unaffected in any way by telluric currents. On testing the latter section, a cable renowned for its extreme immunity from earth currents, a most remarkable phenomenon presented itself. Whilst testing for insulation the deflection of 90deg. would slowly rise to 200, fall to zero, and pass over to the opposite side 80 to 100 divisions of the scale.

The proportion was precisely the same with either twelve silver cells or thirty Menotti's, or with zinc or copper, and with the battery cut off the deflection slowly travelled about the scale exactly as the needles would move were a key drawn backwards and forwards in their vicinity.

After a careful observation I came to the decided conclusion that some magnetic disturbance was taking place, and, remembering my former experience, I remarked to my assistant, and afterwards during the day to several people, that within the twenty-four hours we should have a violent shock of earthquake.

Unfortunately, I could not get this section "freed" again during the day, but, from our difficulty in working, I clearly saw the disturbance continued, and, as I fully anticipated, and to my extreme delight, we had, at 4:10 a.m., one of the smartest shocks felt for the last two years.

By some strange coincidence I awoke to hear a sound similar to a heavy gun being drawn in the vicinity of the house, immediately followed by an increasing oscillation of the earth, which from its strength and duration portended a very violent shock. It lasted, possibly, four seconds, and it fortunately paused half way, giving you the idea of two different shocks, otherwise I am fully persuaded much damage

Digitized by Google

would have been done to the town. Hastily dressing myself, I went down to my testing room with the intention of ascertaining the extent of the disturbance by placing in circuit any one of the cables not in use at that moment; but, precisely as on the former occasion, I found it impossible to get the spot of light to any constant zero, or any rational deflection with the current on the cable in circuit; and only by placing the directing magnet at right angles across the coils could I keep the light anywhere near zero. Later on, in the course of the morning, the galvanometer returned to its normal condition.

In my opinion it is impossible to attach too much importance to this fact, when it is considered that not only were the phenomena observed two years ago identically the same in the present instance, but that by a most fortunate coincidence I predicted, with the greatest confidence, that within the day an earthquake actually would take place.

It is also worthy of note that the direction of the earthquake was nearly due S.E. to N.W., or exactly parallel with the Cretan cable, on which the magnetic disturbance was observed the day previously.

That the introduction of submarine telegraphy has opened a most extensive field for deciding several important scientific questions is indisputable. The immense surface offered even by a short cable serves admirably the purpose of studying and decisively fixing upon the origin and cause of "earth" currents, the presence or approach of thunderstorms, and much valuable information referring to meteorology, besides the more important one, about which so little is absolutely known, of earthquake shocks.

I do not pretend to assert that the observations made have finally decided the question, but being fortunate enough to have the advantage of commanding a perfect "cobweb" of cables, passing all over this part of the world, so subject to earthquakes, I consider it my duty to give to your readers all the information my experience and position can from time to time collect.—Yours, &c., W. G. Forster,

Superintendent Eastern Telegraph Company.

Zante, April 4, 1883.

ELECTRICAL MACHINES AND THE TRANSMISSION OF POWER TO A DISTANCE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: It would have been interesting to have seen the expression of blank astonishment gradually gathering on the face of your contributor whilst he was proceeding with the translation of M. A. Bandsept's letter. The writer begins by referring to Hospitalier's discovery that a leak in the line must have been favourable to Marcel Deprez's experiment, and after remarking that you will perhaps find his notes worthy of attention he informs you that "the complete solution of the problem of the transmission of power does not seem to him to be possible under actual working conditions." This is a gloomy prospect indeed; but, happily, your correspondent shows us how it can be improved. The remedy is to have two different machines, a generator without core and a receiver without wire. There will be no difficulty about the generator; dynamos without an iron core in their armatures have been made, and are fairly good machines. But I am not aware that machines without wire have yet been made. If we only knew how to do this, what large profits could be made on the manufacture of such machines. Perhaps your correspondent will favour the engineering world with a sketch or description of his motor, and thus earn the gratitude of all interested in the electrical transmission of power.

A dynamo the field magnets of which are not excited will, of course, work as a motor, though with very poor results, as I have found from actual experiment; but M. Bandsept must have meant the armature to be without wire, for he goes on to say that "this arrangement would suppress or diminish the counter electromotive force, and thus considerable progress would evidently be made." It would be equally reasonable to suggest a turbine without buckets in order that the free flow of water might not be interfered with. The writer is evidently not aware of the fact that the counter electromotive force is one of the elements which determine the amount of mechanical energy developed by the motor. To make his way of looking at the question perfectly clear, he gives a mechanical illustration by comparing the dynamo to a centrifugal ventilating fan. Why a couple of fans connected by a pipe should be "one of the most striking analogies of electricity" is, however, not quite so easy to see; and no engineer would ever dream of transmitting power by centrifugal fans—that is, not until he had discovered how, when "any obstacle compels the dynamic centrifugal action to alter its potential, the dynamical reaction thereby necessarily produced" can be done away with. What that exactly means I do not know, but M. Bandsept informs us that this desirable result can be attained by "simply so arranging matters that the air-current shall arrive at the paddles of the second fan at the exact moment when the transformation of the dynamical action is taking place there."

All this is puzzling enough to the average engineering mind, but the last part of the letter will, I venture to think, even puzzle the greatest men of science. A new problem is here darkly hinted at, and it seems to be this: Why not condense the electricity after it has passed through the machine? "We condense steam when it has given up its useful work; and are not our most powerful engines worked on this system?" The letter concludes with a recommendation to those interested to prosecute their researches in the direction indicated.

This last sentence makes me almost think that the whole letter is a practical joke intended for the special edification of some very young and innocent, but at the same time, very zealous disciples of electrical science.—Yours, &c.,

April 21, 1883. Gisbert Kapp.

INSULATING ELECTRIC LIGHT WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: With reference to the notice in your last issue of an invention by Messrs. Phillips, embodied in a patent for "making insulating bodies of electric light conducting wires non-inflammable," I should like to correct the impression that the application of tungstate of soda for the said purpose is novel. It is now more than twenty years ago that this substance was introduced into commerce for the protection of tissues and other substances against fire, and its application has been described in detail in Hofman's "Report by the Juries of the International Exhibition, 1862." Since then its use has been extended to various objects for this identical purpose. Therefore, it does not seem as if the application of tungstate of soda to rendering even those materials non-inflammable which were relatively little known at the time referred to could properly form the subject of a patent or be styled an invention.—Yours, &c.,

23, Burton-crescent, W.C., Chemist.

23rd April, 1883.

REIS'S TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: It may, perhaps, interest the readers of *The Electrician* to read the *prospectus* which Reis issued with his telephones in August, 1863, of which I enclose for your inspection an original print, together with the accompanying translation. I may add that a copy of the prospectus (reprinted in Pisko's "Recent Apparatus of Acoustics") has been in the British Museum for the last dozen years, and another copy in my own possession for seven years. Written one month later than the letter to Mr. Ladd which has so lately been reprinted in your columns, it explains several of the obscurities in that letter. It is valuable also as showing, amongst other things, the function of the auxiliary apparatus which Reis used as a call-signal, and which in his letter to Mr. Ladd he had styled the "complementary telegraph."

The question raised by the letter of Mr. Farquhar in

Digitized by Google

your columns as to whether the existence of this telegraphic signalling apparatus did not show that the instrument was intended only to transmit music is most satisfactorily answered by the prospectus and by the figures. In the first place, had the "complementary telegraph" been intended to make up for supposed deficiency of the telephone it would have been placed at the side of the receiving, not of the transmitting part of the apparatus. Its position at the side of the transmitter shows that it was put there to enable the person who was listening at the receiving end to telegraph back to the person who was singing or talking at the transmitter.

Further, the instructions given for signalling are a sufficient reply in themselves to the question raised by Mr. Farquhar. If the person who is listening to the receiver wants the person at the transmitting end to *talk*, he signals *two* strokes; if he is to *sing*, *one* stroke is signalled.

Lastly, a most curious commentary on Reis's utter unfamiliarity with the technicalities of telegraphy is afforded by the code which he suggests for the use of the person who wants to signal through the "complementary telegraph." Yet the Morse code was known in Germany long before 1863.

—Yours, &c.,
SILVANUS P. THOMPSON.

April 21, 1883.

REIS'S PROSPECTUS.

(Translation.)

Telephon.

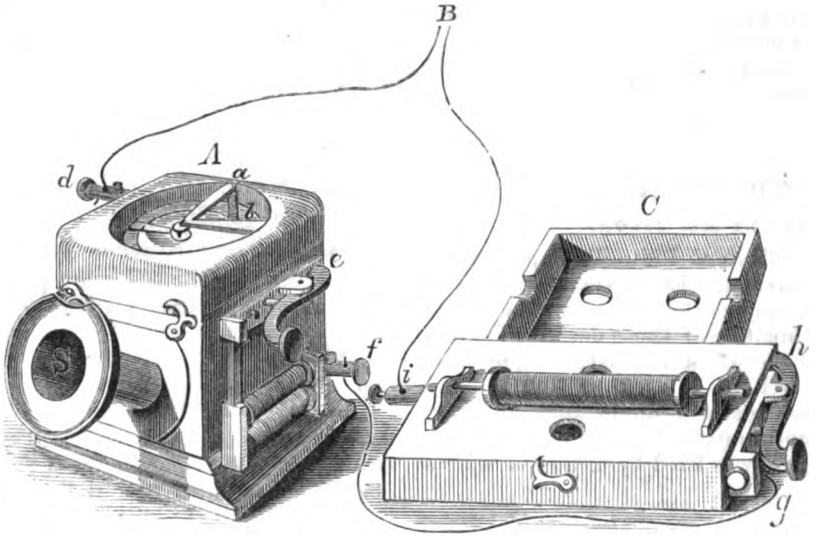
the circuit will be once opened and again closed for each full vibration, and thereby there will be produced in the iron wire of the spiral at Station C the same number of vibrations which there are perceived as a tone or combination of tones (chord). By imposing the little upper-case [oberkästchen] firmly upon the axis of the spiral the tones at C are greatly strengthened.

Besides the human voice (according to my experience) there can also be reproduced the tones of good organ pipes from F — $\overline{\overline{c}}$, and those of a piano. For the latter purpose A is placed upon the sounding board of the piano (of thirteen triads, a skilled experimenter could with all exactness recognise ten).

As regards the telegraph apparatus placed at the side, it is clearly unnecessary for the reproduction of tones, but it forms a very agreeable addition for convenient experimenting. By means of the same it is possible to make oneself understood right well and certainly by the other party. This takes place somewhat in the following manner. After the apparatus has been completely arranged one convinces oneself of the completeness of the connexion and the strength of the battery by opening and closing the circuit, whereby at A the stroke of the armature, and at C a very distinct ticking is heard.

By rapid alternate opening and closing at A, it is asked at C whether one is ready for experimenting, whereupon C answers in the same manner.

Simple signals can by agreement be given from both



Facsimile of illustration of Reis's Apparatus, taken from his Prospectus.

Each apparatus consists, as is seen from the above illustration, of two parts; the telephone proper A, and the reproduction-apparatus [receiver] C. These two parts are placed at such a distance from each other, that singing or the tones of a musical instrument can be heard from one station to the other in no way except through the apparatus itself.

Both parts are connected with each other, and with the battery B like ordinary telegraphs. The battery must be capable of effecting the attraction of the armature of the electromagnet, placed at the side at station A (3-4 6in. Bunsen's elements suffice for several hundred feet distance).

The galvanic current goes then from B to the screw *d*, thence through the copper strip to the little piatinum plate at the middle of the membrane, then through the foot *c** of the angular piece to the screw *b in whose little concavity a drop of quicksilver is put*. From here the current then goes through the little telegraph apparatus *e-f*, then to the key of Station C, and through the spiral past *i* back to B.

If now sufficiently strong tones are produced before the sound-aperture S, the membrane and the angle-shaped little hammer lying upon it are set in motion by the vibrations;

* *c* is not shown in the original of this illustration, and does not, therefore, appear in our engraving, but readers will readily see where it should be.—ED. *E.*

stations by opening and closing the circuit one, two, three or four times. For example,

1 beat = sing.
2 beats = speak, &c.

I telegraph words thus that I number the letters of the alphabet, and then transmit their numbers:—

1 beat = A,
2 beats = B,
3 „ = C,
4 „ = D,
5 „ = E, &c.

Z would accordingly be designated by 25 beats.

This number of beats would, however, appear wasteful of time and would be uncertain, wherefore I employ for every five beats a dactyl-beat (dactylusschlag), and there results:

— ∪ ∪ for E,
— ∪ ∪ and 1 beat for F, &c.

Z = — ∪ ∪, — ∪ ∪, — ∪ ∪, — ∪ ∪, — ∪ ∪, which is more quickly and easily executed, and easier to understand.

It is still better if the letters are represented by numbers which are in inverse proportion to the frequency of their occurence.

Friedrichsdorf, near Homburg-by-the-Height, Aug., 1863.

PHIL. REIS,
Teacher at L. F. Garnier's Institute for Boys.

"OUR MAGAZINE."

TO THE EDITOR OF THE ELECTRICIAN.

SIR: *Re* my letter of April 7 and your reply in *Electrician*, No. 22, April 14, it is thought by some of us that the officials are now sufficiently strong to carry on a new magazine, and, as your *Electrician* is so widely circulated amongst us, that it is the best medium for inviting suggestions from them.

We are certainly desirous of trying it, as the service is so very different now to what it was thirty years ago.—Yours, &c., LEIGHBOURNE.

[To explain this letter we may say that our correspondent wrote to us suggesting that those employed in the work of the Postal Telegraph Department might now, with a better chance of success than resulted from previous efforts, support a magazine of a social and literary, rather than a technical, character. We hesitated to give a favourable opinion on the question, but it will be seen that our correspondent thinks us mistaken in our views, and we shall be glad to find that this is the case.—ED. *E.*]

HOW IT CAN BE DONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should say that "Jer. Diddler" would have some difficulty in finding a "suitable" friend, *i.e.*, one willing to pay for Jeremy's lighting as well as his own. If the meters are all connected up to the mains in the same manner (as no doubt they would be), it is obvious that the current must pass through one or other of their meters, the friend's, of course, for choice.—Yours, &c., W. M. S.

MICROPHONIC CONTACTS.

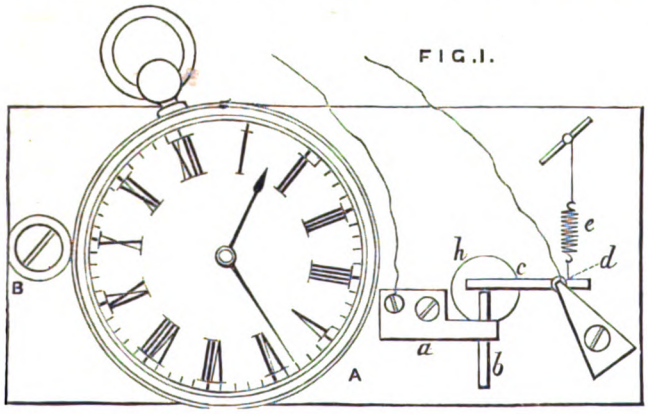
EXPERIMENTS BY MR. STROH.

After the reading of Mr. Shelford Bidwell's Paper* at the Society of Telegraph Engineers and Electricians, on the 12th inst., Mr. Stroh gave an account of the following experiments which he had made in continuation of those described by him at the society's meeting on the 8th March last, and published in our issue of the 17th March.

The microphone used was again of the hammer-and-anvil pattern, this form being most suitable for experiment.

On a little board, A, Fig. 1, was fixed by means of a brass

FIG. 1.



holder, *a*, a thin carbon rod, *b*. Against the end of the latter rested loosely another carbon rod, *c*, which was mounted on a little spindle, *d*. A small spiral spring, *e*, served to vary the pressure at the contact between the two carbons *b* and *c*.

The object of this arrangement was that the points of contact might be brought under a microscope, and for that reason the carbons, where they came into contact with each other, were made as flat as possible, and also thin at the edges, so that they might be fairly brought into the focus of the microscope.

The little board A, on which was placed a loud ticking watch as a source of sound, was fixed, at B, on a stand apart from that of the microscope, so that touching and adjusting the latter might not interfere with the microphone. A hole in the board at *h*, under the contact, was necessary to admit light from below.

In the circuit with the microphone were a telephone, a make-and-break key, and a small battery of one to three cells.

The two edges of the carbon contact appeared, although they were made with care, rough and jagged through the microscope, as represented in Fig. 2, and before the current passed, one or two of the projecting points were seen in contact only.

The tension of the spring for the first observation was such as was known by experience to be necessary to insure microphonic contact. By depressing the key, a current from two cells was now sent through the circuit, and the effect was closely observed by means of the microscope. What was noticed was a light, or, in fact, a burning away of the carbon; the two carbons came closer together during that burning, and presently another contact was made, and another light became visible. The carbons still approached, until three or four points were in contact, each of which was illuminated, and at last, as it appeared, when there were a sufficient number of points of contact for the greater portion of the current to pass, then the burning ceased, and the ticking of the watch could be heard in the telephone.

All this took place in the course of a few seconds; and while the microphonic condition remained no light could be seen at the points of contact. But as soon as the battery power was increased the burning commenced again, and continued until the area of contact was sufficiently enlarged, and consequently the resistance so far reduced that the

FIG. 2.

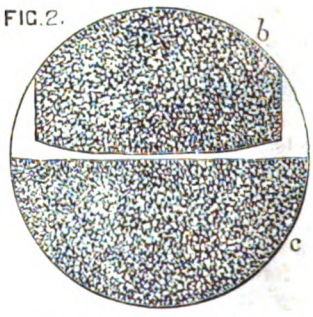


FIG. 3.

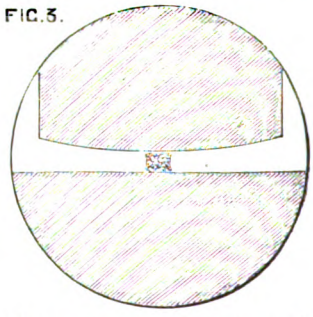

degree of heat which was still produced was below that which causes the combustion of the carbon.

This agrees with Mr. Bidwell's observation, viz.:—That the resistance of the contact falls with an increase of current.

The pressure at the contact was now reduced to a minimum by letting down the tension spring, so that the two carbons were only just in contact and no more, and when a current from the two cells was allowed to pass, a momentary burning at the contact, accompanied by a click in the telephone was observed; then followed an interruption, and the current would pass no more.

By making contact with the key many times, no trace of current could be detected with the telephone, showing that after the first passage of the current great resistance was established. This is also an effect observed and investigated by Mr. Bidwell.

The tension spring was now slightly tightened; this evidently caused the insulating film or substance which prevented the current from passing to be forced aside or broken through, for another current passed on making contact, but only for a moment, and then again an interruption occurred. This could be repeated several times, until the spring was wound so tight that the insulating substance was broken through as soon as it was formed, and then the well-known boiling or hissing noise which we hear when the microphone is out of adjustment could be heard in the telephone. Sometimes the noise was a perfectly clear, musical note, and by adjustment of the spring it occasionally became as shrill as a whistle.

It was found possible to adjust the microphone so that while still listening to the noise the watch could be heard as well, and whenever this was successfully accomplished the

* Part of this Paper appeared in our last, and the remainder will be found in another column of our present issue.

Digitized by Google

tick of the watch was heard louder than under any other circumstances.

That experiment was made with a telephone of considerable resistance, which was now replaced by one of a very small resistance, only a few ohms, and an entirely different effect was obtained.

The spring was again let down, so that the carbons were only just in contact. A momentary burning was seen as before on passing the current, but the movable carbon was also driven away from the fixed carbon, and apparently remained repelled at some distance. Each time the circuit was completed by the key the movable carbon was repelled, and a continuous stream of sparks could be seen flying across the space.

The sound produced in the telephone by this effect resembled the crackling of burning wood. By tightening the spring the noise was frequently changed into a musical note, the pitch of which rose with the pressure.

By closer observation exceedingly fine dark lines could be seen which reached from every projection of the jagged edge of the loose carbon, right across the space to the fixed carbon. This showed that the movable or loose carbon was in a state of vibration, the amplitude of which was equal to the distance of the apparent separation of the two carbons.

This distance, which was considerable when the rate of vibration was low, became rapidly less as the rate was increased by tightening the tension spring, and a point was soon reached when the separation could no longer be seen, but was likely still to exist during the production of the higher sounds.

Another effect which was occasionally observed with the microscope during the production of the various noises above mentioned was that little fragments of carbon which probably became detached by their expansion by heat, but still remained between the electrodes, were in a state of agitation.

There can be no doubt that during the production of these singing, hissing, or boiling noises, the current cannot be a constant one, but that in the case of the former it must be intermitted and of equal periods, while in the case of the latter it is probably undulatory and of unequal or irregular periods.

It also appears evident that a current crossing a microphonic contact has a strong tendency to cause vibratory disturbances, and it seems, therefore, reasonable to suppose that during microphonic action, even when all is in good adjustment, the sound waves which are transmitted are accompanied by other vibrations which are due to the passage of the current itself.

The following reasoning has led to this supposition. Whenever it was possible to adjust the microphone so that the ticking of the watch could be heard during the production of singing or hissing noises, the *timbre* or quality of the sound of the ticking was exactly that of the hissing noise, and any change in the character of the latter was always accompanied by a corresponding change of the former.

It being a fact that sudden slight changes in the quality of sound are sometimes observed even when the adjustment of the microphone is perfect, that is to say, when no singing or hissing noises are heard, it must be that, whenever sound-waves are transmitted, these have super-imposed upon them other vibrations, possibly of a very high rate or pitch, which vary, and so produce change of *timbre* or quality. The latter would be the vibrations or disturbances produced by the passage of the current across the contact.

In the next experiment metallic contacts were substituted for the carbon ones. With platinum very good microphonic effects have been obtained whenever sticking could be avoided.

With a view to prevent sticking, a little oil was placed on the platinum contacts, but quite a different and unexpected phenomenon was observed. The oil by its capillary attraction of course remains surrounding the contact, and when the adjustment was made so that the ticking of the watch could be heard, little particles of dust or carbon which happened to be in the oil were seen in violent agitation, and to be spinning round with great rapidity.

It was puzzling for a time as to what caused the particles to be agitated in so violent a manner, but it appeared afterwards that it was probably the effect of heat. The oil seemed to be boiling at the point of contact even with a single cell, and when an exceedingly fine thread of smoke was observed arising from the contact it became evident that such must be the case.

A number of carbon particles were then placed upon the oil, and when the current was again sent through and allowed to continue for a minute or so, the whole of the carbon dust, which was at first violently rotated and started in all directions, accumulated by degrees round the point of contact, and at last built up a pillar which forced the electrodes wide apart and took the shape shown in Fig. 3.

Steel contacts were now substituted for platinum, and with them the same experiments turned out equally successful, but another curious phenomenon was observed—the black particles in the oil continued their movements for a considerable time after the current had been interrupted by the key. In some cases it took quite two minutes before they came entirely to rest.

Having also ascertained that a pillar could be formed with and without the carbon dust in the oil, the latter was now taken away altogether, and it was found that by a little humouring a pillar could be caused to grow even when the contacts were perfectly dry and clean.

This pillar while in course of formation had the appearance of being in a state of low incandescence, but it was concluded afterwards that it was only surrounded by a dull, red glow, which appeared to be really a succession of sparks running along the surface of the pillar.

In concluding his remarks, Mr. Stroh said that he does not think at present that the formation of the pillar is directly connected with microphonic action, but regards it more as a secondary effect. He deems it advisable, however, that all observed effects should be recorded, and that by collecting and compiling them we may help in time to unravel the mystery which still surrounds microphonic contacts.

AN EPISODE IN THE EARLY HISTORY OF THE TELEGRAPH.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.

(CONCLUDED FROM PAGE 539.)

All these experiments, conclusive as they were, had nevertheless little effect in advancing Alexandre's interests; they drew on him the commendations of the multitude, made his name known, but contributed nothing towards the attainment of his end, which was Paris, and the patronage of the First Consul, to whom only would he confide his secret. Having no money for the further prosecution of his plans, he now entered into partnership with a M. Beauvais, who was to supply all sums necessary, and to receive in return a quarter of the profits of the enterprise, Alexandre keeping to himself the secret of his invention until he had netted 60,000 francs by its exploitation, after which it was to become joint property. No sooner were these terms concluded than Beauvais, provided with the official accounts of the experiments at Poitiers and Tours, addressed himself to Napoleon, and solicited the honour of a trial in his apartments and in his presence alone. Napoleon, perhaps smelling gunpowder, declined the meeting, but referred the papers to Delambre, the illustrious academician and astronomer, who, some weeks later, returned a report of which the following is a free translation:—

"Report of Citizen Delambre on the Secret Telegraph of Citizen Alexandre, submitted to the First Consul by Citizen Beauvais:—

"The papers which the First Consul has charged me to examine do not contain sufficient details to enable me to form an opinion, nor, after the two interviews which I have had with Citizen Beauvais, am I able to do more than offer the merest conjectures on the advantages and disadvantages of the Secret Telegraph.

"Citizen Beauvais knows the secret of Citizen Alexandre, but he has promised to impart it to no one but the First Consul himself. This circumstance must make any report from me valueless, for how can one judge of a machine which one has neither seen nor understands?

"All that we know is that this telegraph is composed of two similar boxes, each having a dial, round whose face are marked all the letters of the alphabet. By means of a winch or handle the pointer of one dial is moved to any desired letter or letters, and, at the same instant, the pointer of the other dial repeats the

Digitized by Google

same movements, and in exactly the same order. When these two boxes are placed in two separate apartments two persons can write and reply without seeing each other, and without being seen, and in such a way that no one can doubt the correspondence, which, moreover, can be carried on at any time, as neither night nor fogs can intercept the transmission.

"By means of this telegraph the governor of a besieged place could carry on a secret and continuous correspondence with a person four or five leagues distant, or even at any distance, and communication can be established between the two boxes as readily as one can hang a bell *(qu'on poserait un mouvement de sonnette)*.

"The inventor carried out two experiments with his machines at Poitiers and at Tours, in presence of the prefects and mayors of the respective places, and the official reports of these functionaries attest that the results were completely successful. Now, the inventor and his associate ask either that the First Consul will be pleased to permit of one of the boxes being placed in his apartment, and the other in that of the Consul Cambaceres, so as to give to their experiments all the *éclat* and authenticity possible; or, that he will accord an audience of ten minutes to Citizen Beauvais, who will then communicate to him the secret (of the telegraph), which is so simple that the bare description will be equivalent to a practical demonstration. They add that the idea is so natural as to leave little room to fear that it will ever occur to any *savant*. It is said, however, that Citizen Montgolfier divined it, after some hours' reflection, on a description of the apparatus which was given to him.

"After this statement, which is the substance of my conversations with Citizen Beauvais, a very few remarks must suffice. If, as one would be inclined to believe from the comparison with bell-hanging, the means employed comprised wheels, levers, and such like,* the invention would not be very surprising, and one could easily imagine the practical difficulties that would be encountered as soon as it was attempted to employ it over distances of several leagues.

"If, on the contrary, as the official report from Poitiers seems to show, the means of communication is a fluid, the inventor deserves much more credit for having discovered how to utilise it so as to produce, at any distance, effects so regular and so unfailing. But then one may demand, what guarantee have we for these effects? Neither the experiments at Poitiers, nor those at Tours, in which the distance was only a few metres, supply it. No more would the proposed experiment between the chambers of the First and Second Consuls. So long as the motive power remains a secret, one can never vouch for more than what one sees, and it will be entirely wrong to conclude, from the success of an experiment on a small scale, that like results will be obtained over more considerable distances. If the effect is only attainable at a distance of some few metres the machine ought to be sent to the scientific toy shops.

"If Citizen Beauvais, who offers to defray the expenses of an experiment, had proposed to carry it out in presence of commissioners appointed for the purpose, there could be no objection to granting his request; for, although an experiment on a small scale would not be very conclusive, still, it would enable us to see what might be hoped from a trial of a grander and more expensive nature. But Citizen Beauvais, without expressly decling a commission, desires, in the first place, to secure the testimony and approbation of the First Consul. It only remains, then, for the First Consul to say whether, in view of the little chance of success attaching to an invention so little proved, and announced as so marvellous, he will spare a few moments for the examination of a discovery of an artist, who is described as one as full of genius as he is devoid of scientific learning and of fortune.

"He makes a secret of his discovery, and I ought to judge it with severity, and according to the laws of probability; but the limits of the probable are not those of the possible, and Citizen Alexandre must be sure of his facts, since he offers to expose all to the First Consul. It, therefore, only remains for me to hope that the First Consul will grant him an audience, and that, in the sequel, he will have reason to welcome the inventor, and recompense worthily the author. "DELAMBRE.

"Paris, 10 Fructidor, an X."

With this most interesting document ends the story of the *Secret Telegraph*. In 1806 Alexandre was at Bordeaux taking out a patent for a machine for filtering the water of the Garonne for supplying the city; but, although the authorities seem to have afforded him every facility towards the accomplishment of his scheme, it was never carried out, through want of money. We next hear of him in 1831, when he submitted to the King, Louis Philippe, a project for steering balloons. He died soon after at Angoulême, leaving a widow, who died in 1833, at Poitiers, in extreme want.

Such is the sad story, as told by M. Gerspach, of one who must be regarded as a veritable pioneer in electric telegraphy; for, although Alexandre chose to surround his invention with an air of mystery, and preserved only too faithfully the secret of its action, we believe that he had, in effect, constructed a telegraph of the ABC sort, with static electricity as his motive power. Let us recollect that while he was still a young man, the invention of the Chappe semaphore and its wonderful performances were the theme of daily conversation; and that rival plans were being frequently started—some, semaphores more or less like Chappe's, and for night as well as day service; some, based on the properties of acoustics; and some again, on those of electricity. What more natural, then, than that Alexandre, a clever mechanician, and a man of a quick and vigorous imagination, should turn his attention to the subject.

Now, let us regard the apparatus as described by M. Cochon, in connection with the half admission that electricity was its basis, and that it was operated by a winch or handle, as mentioned by Delambre. Do not this handle, the box, the dial on the top, and the conductor recall the telegraph of Lomond, which was the wonder of Paris in 1787, and which has been already described in these pages.* The dial of Alexandre, it is true, is an immense improvement on the pith-ball indicator of Lomond, but that, too, had its prototype in the synchronous clockwork dial with which Chappe essayed an electric telegraph in 1790, and which, no doubt, was equally well known as the machine of Lomond. Indeed, the inference to us seems irresistible, that Alexandre took Lomond's and Chappe's contrivances as his basis, and built upon them his own improvements.

The only point that remains for consideration is, how did the working (? revolving) of the handle actuate the pointers? The explanation to our mind is not far to seek. Given an electrical machine inside the box, and a train of wheels behind the dial and in gear with the pointer, and it would be easy for a clever mechanician to make the repulsion of a sort of pith-ball electrometer (acting also as a pawl) against a discharging surface, and its subsequent collapse, give motion of a step-by-step character to the wheels, and, through them, to the pointer. The prime conductors of both machines would, under our supposition, be connected by a wire (probably concealed from view), and thus the movements of one pointer would be synchronous with those of the other.

Some writers, as Cézanne (*Le Cable Transatlantique*, Paris, 1867, p. 32), and Berio (*Ephemerides of the Lecture Society*, Genoa, 1872, p. 645), think it likely that Alexandre used the electricity of the pile, then newly discovered by Volta; but this is highly improbable, for, except in the form of the dry-pile, or through the intermedium of electro-magnetism, both of which were not then known, any number of cells that he could enclose in the box would be entirely inadequate to the observed effects. The use of a handle is of itself almost conclusive of the fact that an electrical machine was the active principle.

If we compare this machine with that constructed by our own Ronalds 14 years later (1816), it must be admitted to be decidedly superior; for while it was equally efficient as Ronalds', it was far simpler in construction. Of course neither instrument could be practicable over long distances, as we all know now.

* Forming, in fact, a kind of mechanical telegraph like the railway semaphores of to-day.

THE CHEMISTRY OF THE PLANTÉ AND FAURE ACCUMULATORS.†

PART V.

1. *Influence of Strength of Acid.*

In the second part of this communication in *Nature*, Vol. XXV., p. 461, when treating of the charging of the cell, we pointed out that in the electrolysis of dilute sulphuric acid between lead electrodes, two totally different reactions might be obtained. The positive metal becomes thinly coated with lead sulphate when the current employed is of small density, but with lead peroxide when the density of the current is of greater magnitude. This latter action is, of course, what takes place in the ordinary formation of a Planté battery. The chemical change, therefore, which goes on at the positive electrode is to a certain extent dependent upon the strength of the current. It appeared also of both theoretical and practical interest to

* That is, of Mr. Fahie's History. For all that is known of Lomond's Telegraph see Highton's *Electric Telegraph; its History and Progress*. London, 1852, p. 41.—ED. *E.*

† Reprinted from *Nature* for April 19. Parts I. and II. will be found reprinted from the same source in *The Electrician* for March 25, 1882, p. 309, Vol. VIII., and Parts III. and IV. in our issue for November 11, 1882, p. 612, Vol. IX.

Digitized by Google

determine whether the chemical change was also influenced by the strength of the acid employed. Our experiments consisted in passing a current of uniform strength, about 1 ampere, between electrodes of lead, 12 square inches in size, in varying strengths of sulphuric acid, and estimating in each case the amount of oxygen fixed by the positive electrode. We determined this for successive five minutes of time, and as such actions are not always very uniform, we made in each instance more than one experiment. The results are given in the following table :—

Strength of acid.	Expt.	Percentage of oxygen fixed.				
		First 5 mins.	Second 5 mins.	Third 5 mins.	Fourth 5 mins.	Total.
1 to 5	I.	38·1	28·6	28·6	33·3	128·6
	II.	39·5	30·2	25·6	30·2	125·5
1 to 10	I.	43·4	38·7	29·2	34	145·3
	II.	44·1	39·3	29·3	34·9	147·6
1 to 50	I.	48·3	39·6	35·3	22·4	145·6
	II.	46·2	43·9	23	30	143·1
	III.	54	40	35·3	35·5	165
1 to 100	I.	42	38·3	33·9	29·5	143·7
	II.	42·4	40	37·8	35·5	155·7
	III.	51·1	44·2	34·9	34·9	165·1
1 to 500	I.	46·6	32·6	27	27	132·6
	II.	46·4	27	27	18	118·4
1 to 1000	I.	90·6	81·1	76·4	57·5	305·6
	II.	90·8	77	72·3	63·1	303·2

It appears from this that the strong sulphuric acid (1 to 5) is not quite so favourable to the action as the more dilute (1 to 10), but that between this latter proportion and 1 to 500 there is no great difference in the amount of oxygen fixed, and, therefore, of corrosion of the plate. The appearance of the plate in every instance indicated the formation of only lead peroxide. With sulphuric acid diluted with 1,000 parts of water, the amount of oxygen fixed, and, therefore, of corrosion, was at least doubled, while the chemical action was very different. On parts of the electrode, streaks of a mixture apparently of the yellow and puce-coloured oxides were seen. On other parts a white substance formed and was easily detached, falling in clouds into the liquid. Where this latter action took place, the plate was visibly the most corroded. This white substance gave an analysis SO_4 equivalent to 73·6 per cent. of lead sulphate, suggesting the idea that it was a basic sulphate of the composition $2\,PbSO_4, PbO$, which would require 73·1 per cent. As the peroxidation of the lead is required, and the corrosion of the plate is to be avoided as much as possible, it is evident that this extremely dilute acid must be avoided. It has already been shown that if the sulphuric acid is entirely removed from solution, as sometimes happens in an accumulator, the lead is simply converted into the hydrated protoxide, and therefore corroded without any good effect.

2. *Function of Hydrogen.*—In the formation of a secondary cell, after the complete reduction of oxide or sulphate to metallic lead, bubbles of hydrogen gas are seen to escape from the lead plate. It has been assumed that a portion of this is occluded by the lead, or in some other way enters into association with it, and it has been supposed that this hydrogen compound may play an important part in the subsequent production of electromotive force. It therefore appeared desirable to obtain experimental evidence as to whether hydrogen is so absorbed. The process we adopted for this purpose was founded upon the observation of Graham that hydrogen associated with palladium reduced ferri to ferro-cyanide of potassium, and that generally in the occluded condition the element was more active chemically. We had previously ascertained that hydrogen associated with other elements, as platinum, copper, and carbon, was capable of reducing potassium chlorate to chloride. This method seemed to give trustworthy results, and therefore we applied it in this instance. As the result of several trials, however, we found that the amount of hydrogen associated with the reduced lead was almost inappreciable. Small as this quantity is, however, it is by no means impossible that it may be the cause of the exceedingly high electromotive force observed for the first few moments, on joining up a completely formed cell immediately after its removal from the circuit of the charging current. This, however, may be due, as Planté imagined, to the gaseous hydrogen itself. The principal if not the only function of the hydrogen of the water or sulphuric acid is, therefore, that of reducing the lead compounds.

By a totally different process Professor Falkland has very recently come to the same conclusion as ourselves in regard to the exceedingly small amount of occluded hydrogen.

3. *Evolution of Oxygen from the Peroxide Plate.*—Planté noticed a small escape of gas from the negative plate of his cell immediately after its removal from the influence of the charging current. This he attributed to a decomposition of water by means of local circuits between the peroxide and the subjacent lead plate in contact with it.

The explanation we gave in our first paper (*Nature*, Vol. XXV., p. 221) of the local action which goes on at the negative plate does not account for the escape of any gas—either oxygen or hydrogen. We therefore thought it of interest to ascertain the nature, and if possible the origin, of the gas noticed by Planté.

We found that the escaps of gas from a Planté negative plate was very slight, and soon ceased ; but we observed that it became much more pronounced when the temperature of the electrolytic liquid was raised. In order to get a sufficient quantity of the gas for examination, we prepared a negative plate according to the procedure of Faure, and then heated it in dilute acid, with an arrangement for collecting the gas as it was evolved. The amount of gas was still very small in comparison with that of the peroxide, but a sufficient quantity was collected to enable us to ascertain that it was oxygen. We next heated some of the electrolytic peroxide apart from the lead plate, and again noticed a similar evolution of gas, which was also found to be oxygen. This shows, therefore, that it was not a result of local action.

The gas has generally some odour of ozone, and on testing the dilute acid between the plates of a Planté cell we always found traces of something that bleached permanganate of potassium, and which might be either ozone or peroxide of hydrogen.

The origin of the gas noticed by Planté may be easily attributed to the oxygen which always passes off in quantity from the peroxide plate during the process of "formation." It is only necessary to suppose that some of this becomes condensed on the peroxide, and is gradually eliminated from it when the surrounding conditions are changed. But the matter is capable of another explanation. If peroxide of hydrogen be really formed in the liquid, it will exert its well-known influence on higher oxides, namely, that of reducing them and itself at the same time. As a matter of fact, if peroxide of lead is dropped into peroxide of hydrogen oxygen is evolved.

4. *Temperature and Local Action.*—Planté has recently pointed out that an elevation of temperature facilitates the formation of his secondary cell (*Comptes Rendus*, August, 1882). The character of the chemical changes which took place at the negative plate led us to think it exceedingly probable that this increase in the rate of formation arose from an augmentation in the amount of local action. Experiment showed such to be the case. Pairs of similar negative plates on Planté's model were allowed to remain in repose at 11deg. C. and 50deg. C. respectively, and the formation of the white sulphate was visibly more rapid at the higher than at the lower temperature. The same is also true with negative plates prepared by Faure's process. Thus we found that two similar plates kept in repose for an hour, the one at 11deg. C. and the other at 50deg. C., formed by local action 2·6 and 7·4 per cent. of lead sulphate respectively. On two other plates the proportions were 7·6 and 9·5 per cent. respectively. These observations, of course, by no means exclude the idea that an increase of temperature may facilitate the other chemical changes that take place in the formation of a lead and lead-oxide cell.

J. H. GLADSTONE and ALFRED TRIBE.

THE ROYAL SOCIETY.—The following are the names of the candidates for the fellowship of this society who have been selected by the council to be recommended for election on June 7: —Surgeon-Major J. E. Tierney Aitchison, Dr. J. Crichton Browne, Surgeon-Major G. E. Dobson, Dr. J. Matthews Duncan, Professor G. F. Fitzgerald, Mr. W. Flight, Rev. Percival Frost, Dr. D. Gill, Mr. C. E. Groves, Mr. Howard Grubb, Mr. J. N. Langley, Professor A. W. Reinold, Mr. R. Trimen, Mr. J. Venn, Mr. J. J. Walker. The annual soirée of the society was held at Burlington House on Wednesday evening. Mr. John Evans received the guests in the absence of Mr. Spottiswoode, the President, who is on the continent. Many interesting scientific instruments were shown. Professor Hughes's torsion balance, Stroh's apparatus for illustrating the resemblance between sonorous vibrations and magnetism, Sabine's photometer, and a number of instruments by the Messrs. Elliott were also to be seen. Vice-Admiral Selwyn showed two electrometers, with which he carried out a somewhat novel experiment.

ON MICROPHONIC CONTACTS.*

BY SHELFORD BIDWELL, M.A., LL.B.

(CONCLUDED FROM PAGE 550.)

TABLE IX.

Showing for different pressures the effect of increased current in first permanently reducing the resistance of the carbon contacts, and after a certain point (depending upon the pressure) greatly increasing it.

R_1 = Resistance with current in first column of table.
R_2 = Resistance with very weak current, obtained by inserting 10,000 ohms in the circuit.

·4					3·6	4·2	2·01	2·3
·5					Inf.		1·95	2·2
·6							1·90	2·2
·7							Inf.	

NOTE.—The resistance marked "Inf." was so great that the needle of the tangent galvanometer was not deflected from zero.

The experiments made with metals were less numerous than those with carbon. Metallic loose contacts were found to be even more uncertain in their action than those of carbon, and to obtain a really fair average of results a very great number of measurements would be required. Under precisely the same conditions, as nearly as they could be reproduced, the results obtained were frequently very different. Nevertheless, it has been possible to bring out with sufficient distinctness some remarkable peculiarities in the behaviour of metallic contacts.

The metal principally used was bismuth, which was selected on account of its high specific resistance, but a few experiments were also made with copper and platinum. The cylinders of bismuth and copper were of nearly the same diameter as those of the carbon previously used—6 mm. The platinum was prepared by soldering wires of that metal upon cylinders of brass. The balance already described and shown at Fig. 1 was used in the same manner as before.

The first unexpected phenomenon which attracted notice in working with bismuth was the very great permanent fall in the resistance which was produced by an ordinary current with light pressures. Using a single Leclanché cell, the lightest contact—the pressure being certainly less than ·01 gramme—failed to give a higher resistance than 9 ohms; but with 400 ohms inserted between the battery and the Wheatstone bridge, a pressure of ·35 gramme gave a resistance which on different occasions varied between 73 and 110 ohms. When once, however, the resistance has been reduced by a strong current, the changes which occur when feebler currents are used are comparatively small, unless, of course, the points of contact are first separated. Of the nature of such changes I shall say more presently. Table X. gives a few measurements, using one Leclanché cell—(1) with a resistance of 300 ohms between the cell and the bridge; (2) without the 300 ohms. It will be understood that the bismuth cylinders were separated from each other every time the weights were changed.

TABLE X.

Bridge measurements of the resistance of bismuth contacts under different pressures.

Pressure.	Resistance of bismuth contact with 300 ohms between battery and bridge.	Resistance when the 300 ohms are removed.

5	5·4	1·7
7·5	7·7	·2
10	·8	·8
15	·6	·5
25	·14	·14

The effect in question is most marked with small pressures; with comparatively high pressures it quite disappears.

This phenomenon is accompanied by another. After the passage of the current which has caused the resistance to be so remarkably diminished, the bismuth cylinders are found to adhere to each other, a quite appreciable force being necessary to separate them. This effect, which is common to all metals, has been thoroughly investigated by Mr. Stroh, a description of whose experiments is given in the *Journal of the Society of Telegraph Engineers*, Vol. IX., p. 182. I shall, therefore, say nothing more about it, except that I have succeeded in causing two pieces of very thin platinum wire to stick to each other with a current of about a milliampere. Mr. Stroh attributes the effect to fusion.

* A paper read at the meeting of the Society of Telegraph Engineers, April 12, 1883.

·01	1·22	1·21	1·22
·5	1·27	1·26	1·22
·01	1·22	1·21	1·22

A third apparent anomaly is the following:—A *small* weight being in the scale-pan, let a weak current be caused to pass through the points of contact; the resistance will be found to be high. Let a strong current be passed, and the resistance will begreatly diminished. Once more let the current be reduced to its original strength; the resistance will not rise to its original value; it will not, in fact, rise at all; it will be still further diminished. The following table gives examples of this experiment with pressures of ·5, 1, and 5 grammes. In the last case there is no change after the first fall of resistance.

Table XII. further illustrates the effect with greater variations of current and of weight, but in the experiments to which it relates the strongest current was used at first. As before, the bismuth cylinders were separated only when the weights were changed.

TABLE XII.

Effect of varying current upon the resistance of freshly scraped bismuth contacts.

·5	1·49	1·43	1·61	1·33	1·35

REMARK.—With *clean* bismuth, decrease of current strength is accompanied by decrease of resistance.

In order that this experiment may be successful, it is necessary that the surfaces in contact should be absolutely clean. Unless they are scraped immediately before the measurements are made, the opposite effect may result—that is (after the first great fall of resistance), diminished current may produce increased resistance.

Table XIII. gives the measurements, with the same currents as before, when the bismuth was first rubbed with the finger, instead of being scraped as had been done in the previous experiments.

TABLE XIII.

Effect of varying current upon the resistance of bismuth contacts when the metal has been rubbed with the finger.

·3	1·77	1·72	1·27
·5	1·46	1·45	1·27

REMARK.—When the metal is *not perfectly clean*, decrease of current strength is accompanied by *increase* of resistance.

I think these effects admit of a simple explanation. When the surfaces of the bismuth are clean, contact takes place entirely through the metal. The current heats the metal at the points of contact to an extent which depends partly upon the current strength; and the resistance, in accordance with the general law, increases with the temperature; strong currents will therefore give higher resistance than weak ones. When, on the other hand, the surface is not clean, a film of oxide or some foreign substance is interposed, the resistance of which, like that of carbon, is higher with a weak current than with a strong one.

It is probable that similar effects occur with metals of lower specific resistance than that of bismuth; but their observation is very difficult, and requires more delicate apparatus than that at my disposal. Thus, of 40 measurements made with platinum contacts, 19 results were favourable to the theory, 10 adverse to it, and 11 neutral. With copper the indications were even more uncertain.

Digitized by Google

The resistance of bismuth contacts at various pressures was then measured with fixed currents of ·1, ·01, and ·001 ampere, the method used being the same as in the case of carbon. The mean of several series of such measurements is given in Table XIV., which reveals the existence of a more or less definite law, though the results of the experiments did not agree very closely among themselves.

Repeating with bismuth the experiments already described in the case of carbon, it was clear that the diminution of resistance effected by pressure is generally of a permanent nature, continuing to a great extent after the pressure has been removed (so long as the points of contact remain undisturbed), and thus reversing the case of carbon. With strong currents the variations of resistance were so uncertain and irregular that accurate measurements were impossible; but with a resistance of 300 ohms between the battery and the bridge the effect is very clearly marked. The results of the experiments thus made are contained in Table XV.

TABLE XV.

Showing great permanent effect of pressure upon the resistance of bismuth contacts.

·5	1·5	1·7	·5	4·5	5·5	15

NOTE.—In the last three cases the apparatus for removing the additional weight worked badly, and caused a slight vibration of the scale-pan.

The points of contact were of course changed for each series of observations, and it should be noted that in the case of the last three (which were not made on the same day as the others) I was less successful in arranging the lever so as to secure perfect freedom from oscillation when the weight was changed.

At the meeting of this society, held on March 8, Mr. Stroh gave an account of a method which he had devised for observing the movements performed by the horizontal carbon rod of an ordinary microphone when the instrument is in action. He attached a small mirror to the carbon, from which a beam of light was reflected to a wall, the distance of which was such that the movement of the spot of light was 2,000 times greater than that of the carbon at the point of contact, and it was found that if a current from three bichromate cells was passed through the microphone, when it was so adjusted as to be in the best working condition, the "spot of light remained steadily deflected downwards," moving through a space of one millimetre, and returning to its former position when the current was interrupted. This, Mr. Stroh says, in an article which he has since published (*Electrician*, Vol. X., p. 429), "seems to indicate that during the time when the carbons are really in what is called microphonic contact they are not in contact at all, or, at all events, there is a repellent action at the point of contact."

It occurred to me that additional light might be thrown upon some of the phenomena which I have investigated by the application of Mr. Stroh's method, and I began by repeating the experiment almost exactly as he describes it. I at first found, as he did, that the effect only occurred when the microphone was so adjusted that the ticking of a watch laid upon the base could be distinctly heard in a telephone which was in the circuit. But with the high electromotive force of three bichromate cells it was exceedingly difficult to get the microphone into good working condition, or to keep it so for any length of time. A tangent galvanometer was then inserted in the circuit, and it at once became evident that when the condition of the microphone was at its best the current was strongest. It appeared probable, therefore, that the magnitude of the apparent repulsive effect depended merely upon the strength of the current which was passing at the moment, and that the excellence of the microphonic effect had really nothing to do with the matter. The upper carbon was therefore pressed down with a weight too heavy to admit of the ticking of the watch being heard, and a steady current was thus secured without any difficulty. It was now found that the repulsive effect was almost, if not quite, as great as it was when the carbons were in loose contact, and little doubt was left that the phenomenon was merely a case of expansion due to the heating effect of the current. Cylinders of bismuth were then substituted for the carbon rods, and a similar effect was produced, the movement of the spot of light being somewhat greater than it was with carbon. With copper the apparent repulsion was rather less than with carbon, but perfectly well marked. Lead was then tried, being chosen on account of its high coefficient of expansion and its inferior conductivity for heat and electricity, and, as was expected, the deflection of the spot of light was very considerable, being about six times as great as in the case of carbon.

One or two other curious results are worth noting. In the case of metal contacts, when the pressure was slight, the first effect of a small current was to produce closer contact; as the strength of the current was gradually increased, the contact became more and more close; when the circuit was broken, the Stroh effect occurred, and the contact became apparently still closer. This observation is evidently connected with the fact already discussed, that a current through loose metallic contacts causes a permanent decrease in their resistance. The same thing occurs when carbon contacts are used, but it is well marked only when the contact is exceedingly light, and is, I believe, due to the combustion of the minute projecting particles upon which the carbon rod rests. Finally, an attempt was made to exaggerate the effect by multiplying the number of carbon contacts. Twelve small pieces of carbon shaped like whip-top were arranged in an upright tube of ebonite, which they loosely fitted. The lower carbon was fixed, and the upper one had a knife-edge upon which rested a horizontal carbon rod with a mirror attached. A current through this arrangement produced a deflection five or six times as great as in the case of the single contact. It now became possible to observe that the whole effect was *not* absolutely instantaneous as it had previously appeared to be, a slow movement of the image in the upward or downward direction continuing for two or three seconds after the circuit had been opened or closed. When a single long piece of carbon was substituted for the small pieces the effect was similar, but not so great.

The little carbon balance (Fig. 1) was joined up in circuit with the apparatus just described, and it was observed that with a continuous current the magnitude of the repulsive effect could be varied by altering the weights in the scale-pan. This experiment was much more effective when an Edison carbon telephone was used instead of the balance. Pressing the diaphragm with the finger caused the spot of light to move to an extent depending upon the pressure.

It naturally occurred to me that a *receiving* microphone might easily be made by slightly modifying the apparatus to which the mirror was attached. A dozen top-shaped carbons were placed end to end in a glass tube; the bottom one was sealed in, and attached by a wire to a binding screw; the upper one, which was connected by a wire to a second binding screw, was made to press gently upon the centre of a mica diaphragm, on the other side of which was a steel spring to increase its elasticity. Using 12 Leclanché cells and an Edison transmitter, it was found quite possible to carry on a conversation, and very little adjustment was necessary. The instrument, of course, operates through expansion by heat, the action being exactly similar to that of the platinum wire in Mr. Preece's thermal telephone receiver; and I have little doubt that the operation of all receiving microphones which have been constructed may be explained in the same way.

Application to the Microphone.—The results of the experiments described in this paper may, perhaps, throw some light on a matter which has never hitherto been fully explained. Why does carbon give far better results than any metal when used in the microphone? It seems to me that this question may be very easily answered. The mere fact that a current causes delicately adjusted metal contacts to adhere to each other is sufficient to account for the superior efficiency of carbon. It is possible, indeed, to transmit articulate sounds by means of a metal microphone, as is proved by some of Professor Hughes's earliest experiments, but the action of such an instrument, as compared with one of carbon, is extremely uncertain and imperfect. This is no doubt due to the fact that, although vibrations corresponding to the fundamental tone are easily produced, the minute superimposed vibrations due to the upper partials, upon which depends the distinctive character of a particular sound, are, owing to the adhesion, very imperfectly represented, if not entirely lost.

At a recent meeting of this society Mr. Munro exhibited a metallic microphone, in which, by the ingenious use of iron gauze, the current is divided among a great number of points, at each of which its heating effect is small, and adhesion therefore does not occur to any perceptible extent. But though this instrument may be good enough for practical use, Mr. Munro would hardly contend that its performance is equal to that of a carbon microphone.

In addition to this phenomenon of adhesion, and probably connected with it, are the facts that metallic contacts, unlike those of carbon, do not even approximately recover their original resistance when once it has been reduced by increased pressure or increased current, unless, indeed, complete separation occurs, and even the initial effect of pressure upon resistance is in general much more marked with carbon than with metals.

Lastly, there is the fact that, in the case of carbon, pressure and current act in consonance with each other; pressure diminishes the resistance, and in so doing increases the strength of the current, and the current thus strengthened effects a further diminution in the resistance. In the case of metals, on the other hand (or at least in the case of clean bismuth), pressure and current tend to produce opposite effects. The resistance is diminished by pressure, and the current consequently strengthened; but by reason of the increased strength of current the resistance is *higher* than it would have been if the current had remained unchanged. The effect of this antagonism is not very great, but it seems to give a material advantage to carbon.

In conclusion I think that the results arrived at in this paper may be made to furnish data for designing upon scientific principles a carbon pencil microphone which shall possess the maximum degree of efficiency; and, without entering into details or making any specific calculations, I propose to indicate briefly the lines which should, in my opinion, be followed in order to secure the most satisfactory results. The following questions present themselves for solution:—

(1.) Should the constituent elements of the microphone be few or many?

(2.) Should they be arranged in series or in multiple arc, or in a combination of the two?

(3.) Should they be light or heavy?

Digitized by Google

(4.) Should the pressure at the points of contact be great or small?
(5.) Should the resistance of the system be high or low?
(6.) Should the current used be strong or weak?

Before considering the points here raised it may be well to state definitely what I conceive to be the *modus operandi* of the microphone as used for the transmission of speech.

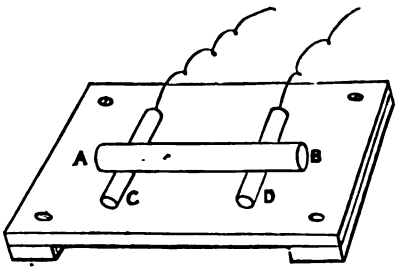

FIG. 9.

Fig. 9 is intended to represent a typical microphonic element. A horizontal carbon pencil, A B, is supported at the ends upon two carbon blocks, C D, which are attached firmly to a sound-board, usually of thin pine. The sound-board is acted upon by air waves, and caused to repeat upon a smaller scale the movements of the air particles which beat against it. It carries the lower carbon blocks with it in its movements, and causes them to press with varying force against the under side of the loose carbon pencil. The varying pressure produces alterations in the resistance at the points of contact, in exact correspondence with the phases of the sound waves, and the strength of a current passing through the system is thus regulated in such a manner as to fit it for reproducing the original sound in a telephone. The loudness of the repeated sound increases with the limits between which the current is made to vary.

Now, if it is true, as this theory supposes, that the whole action of the microphone is due to the motion, or tendency to move, of the lower carbon blocks (the influence of sonorous vibrations upon the loose block or pencil being so small as to be negligible), it follows that, if the variations of pressure are to be considerable, the upper block must be capable of offering resistance to the movements which the lower blocks tend to perform. It will, of course, do this the more effectively, the greater its inertia, and therefore its mass or weight. In order, therefore, to secure the greatest variations of *pressure*, the loose carbon must clearly be heavy.

But with the ordinary arrangement a heavy carbon implies great pressure at the points of contact; and it has been clearly proved that the resistance is far more easily varied when the average pressure is small than when it is great. Here, then, we have two conflicting requirements, and, if the usual arrangement is to be retained, a compromise must be effected, and it will be necessary to ascertain by experiment or calculation what must be the weight of the carbon in order that sonorous vibrations may produce the widest variations of current; remembering that if it is too light the differences of *pressure* will be small, and if too heavy the changes of pressure will give but small changes of *resistance*. But it would, I think, be decidedly better to depart from the usual form, the chief recommendation of which is its extreme simplicity. Many methods will suggest themselves of arranging the materials in such a manner that, while the weight of the loose carbons is great, they may exert but slight pressure against the fixed carbons. Fig. 10 illustrates an example of such

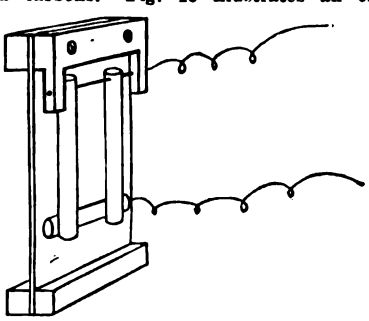

FIG. 10.

an arrangement. The loose carbons are suspended vertically upon a wire (attached to the frame of the instrument) which passes through holes in their upper extremities, their other ends resting lightly upon a horizontal pencil which is fixed to an upright sound-board. This may be mounted in a swing-frame like that of a looking-glass, and the pressure of the carbons adjusted by varying the inclination of the frame. Ordinary ingenuity will suggest other methods of accomplishing the same purpose.

The question as to whether it is preferable to arrange the elements in series or in multiple arc is very easily answered. If the elements are in series, the whole of the current used will pass through each of them; while if they are in multiple arc the current will be subdivided and each element will be traversed by a current the strength of which (supposing them all to be equal) will be inversely proportional to the number of elements. Now, the sensitiveness of the contacts to changes of pressure has been shown to increase greatly with small currents, and hence it follows that the multiple arc is to be preferred to the series system. The same reasoning, in a modified form, will condemn a system in which the series and multiple arc arrangements are combined; for the greatest perfection, therefore, the multiple arc system pure and simple should be adopted.

The high degree of sensitiveness attending the use of small currents points also to the advantage of multiplying the number of the elements. I believe that this number might well be made much greater than is customary, being limited only by considerations of space. The sound-board should not, of course, be too large, or there will be a risk of the sonorous waves reaching different parts of it in materially different phases, especially if their direction is oblique to the surface of the board. But it would not be difficult to arrange 50 or 60 such suspended elements as those shown in Fig. 11 within an area 15 centimetres square. I have made a transmitter upon this plan, in which the suspended elements, forty-five in number, consist of brass tubes filled with lead, and having short pieces of carbon fitted into their lower ends, and I believe its performance is greatly superior to that of most instruments of the kind.

Since the efficiency of a microphone depends principally upon its power of varying the strength of the current in a circuit comprising the microphone, a battery, and the primary wire of an induction coil, it is clear that the electromotive force of the battery should be as high as is consistent with other conditions, and the resistance of the battery coil and microphone should be low; for the proportional change of resistance caused by sonorous vibrations remaining the same, the stronger the maximum and minimum currents, the greater will be the actual difference between them. But for securing sensitiveness it is very important that the current passing through the microphone should not exceed a certain strength, and indeed, if the pressure is light (as it should be), a strong current will, as we have seen, enormously increase the resistance of the contacts, or some of them, thus impairing or utterly destroying the efficiency of the instrument.

The subjects of all the questions with which these observations were introduced have now been touched upon, though no attempt has been made to answer them very definitely. In general we may say that—

(1.) The constituent elements of a microphone should be numerous.
(2.) They should be arranged in multiple arc.
(3.) They should be heavy.
(4.) The pressure at the points of contact should be light.
(5.) The resistance of the microphonic system should depend upon the resistance of the rest of the circuit (which should be small) and upon its sensitiveness to changes of pressure. In general it should be small.
(6.) Up to a certain limit, depending upon the number of contacts and their pressures, the current used should be strong.

It need hardly be added, in conclusion, that the observations which I have ventured to offer do not profess to do more than indicate the merest outlines of the details which should be considered in designing a carbon pencil microphone of the greatest possible perfection.

MAXIM-WESTON ELECTRIC COMPANY (LIMITED).

The ordinary general meeting of the shareholders in this Company was held on the 20th inst., at the City Terminus Hotel, under the presidency of Admiral Sir Edward A. Inglefield, C.B., F.R.S.

The SECRETARY (Mr. Thomas R. Comyn) read the notice convening the meeting, and the report of the directors was taken as read. It stated, *inter alia*, that "The recent Electric Light Bill has not been of benefit to electric light companies (owing to vestries and corporations not yet being in a position to take advantage of its provisions), and other causes have tended to obstruct the use of electricity for lighting purposes. But the directors feel convinced that only further time is necessary to bring it into general use; and, meantime, most valuable improvements have been made in the lamps and dynamos, expenditure curtailed to the utmost, a number of agents appointed, and the Company put in a position to undertake the most extensive contracts immediately when obtained. As some evidence of this, it may be stated that contracts have recently been made with the Science and Art Department for the lighting of the Bethnal Green Museum, with Messrs. Kirk and Randall for the new dock works at Tilbury, with the proprietors of Astley's and the New Grand Theatres, independently of lesser lighting contracts. Several others of an extensive character are now pending, with every prospect of being satisfactorily completed. . . . An agreement has been concluded with an influential syndicate for conditional concessions for the various Australasian Colonies. The value of the stock, &c., at the factory and at the various centres of installation amounts to £21,372, and that of the lease, buildings, and furniture to £2,390. Everything is in a sound, workable state, and a most efficient staff has been organised, capable of undertaking any description of lighting, and at a cost for wages which will compare favourably with any other company. The present contracts for lighting Queen Victoria-street and Southwark Bridge, and for Pentonville-road, are in a satisfactory condition, and there is a probability of both being considerably enlarged on remunerative terms. The Company is now undertaking no unremunerative contracts. With additional capital, the directors see their way to a large and profitable business, and they have thought it desirable to submit for the consideration of the shareholders a proposal to increase the nominal capital of the Company to £500,000, to be issued as required. This will enable the directors to extend the Company's operations to the numerous towns and districts still unrepresented, and pave the way for concessions. They also propose to commence the manufacture of dynamos, which must prove a lucrative source of revenue."

The CHAIRMAN, in moving the adoption of the report and balance-sheet, said he had not the least doubt that during the meeting there would be so much discussion on every subject that perhaps if he were to enter into any lengthened statement as to the progress of the Company since their last meeting it might only result in repetition. He thought, however, he might outline what he had to say by simply stating that since the last meeting the directors had done their utmost to further the interests of the Company. They had met with considerable difficulties. The shareholders probably knew that the City lighting business had not been a successful matter in a commercial point of view, but that it had been successful as regarded proving the value of the light and of the Company's system he thought none of them could have the least doubt. The question had been frequently raised as to how it was that the Company, having had a good many orders, and apparently done a certain amount of business, had now arrived at the position of not having capital to carry on. He thought he had better state at once in a few words that that condition of affairs had resulted first of all from having an entirely new business to conduct; in their having taken over in the first instance a very extensive contract as part of the business of the Company, by which they had had a serious loss—he alluded to the City lighting; from having to pay to the promoter of the Company £70,000 before they could commence business; and in purchasing then the Lontin system without any incandescent system, in which respect they were in a position different from that of any other company which had obtained both arc and incandescent systems. However, finding themselves without

Digitized by Google

an incandescent lamp they were offered for a very large sum the purchase of the Maxim and Weston patents. They might ask, Why did you not purchase the Maxim, having an arc lamp, and not acquire the Weston? The answer was, Simply because they were to be bought together or not at all. They, however, brought the price down to about half. Though the directors had the power to close with that purchase without consulting the shareholders they thought it better to do so, and they might remember that they at once gave their consent, though the directors hinted that, having to pay £52,000 out of what they thought was working capital, it might possibly be necessary to increase the capital. He, however, also held out to them hopes that by selling their patents to subsidiary companies they might obtain, as in the case of another large company, sufficient money not only to carry on the business but to declare dividends and do as other companies had done, work successfully without raising further capital. He might remind them that out of the forty-four companies formed thirty-four had a larger capital than this Company had at starting, and perhaps the greatest mistake they had made was in not having a larger nominal capital on forming the Company. However, taking things as they were they found themselves, having paid £70,000 in the way of purchasing patents which they did not now use, of installing the City lighting, and of purchasing a new incandescent and arc system—they found themselves with very little money to carry on with, and yet so far they had succeeded in going on without getting into debt. The failure in connection with the subsidiary companies was due to two or three reasons. One was because they adopted the customary plan of using promoters, who were interested in the parent Company, and who undertook, on certain terms, to bring out a subsidiary company. He was not for one moment going to condemn the system of promoters, as it was almost essential in bringing out companies that there should be promoters. There were many things which had to be done only through a promoter. A promoter had to lay out a large sum of money of his own, which he must expend to bring out a company, and if it did not float he himself had to pay. It was, therefore, very natural that he should be protected against such an event. First, they started an Australian Company, but, owing to difficulties, that company never floated. Everything was done on the part of the Board, and every point they thought fair was agreed to. That company, however, did not float. An Indian Company fell through very much in the same way. At last the company which had floated was formed by the parent Company, and carried out by two of the directors. For that reason he, as chairman of this Company, was also a director of the Lancashire Company — a point which had sometimes been referred to as an extraordinary thing. That company had been floated, and had paid a large sum of money to the parent Company, and if all the calls which were due were paid, as they ought to have been by now, the parent Company would have had some £3,000 or £4,000 more than it had had. They had done their utmost by the means he proposed before—by subsidiary companies—to prevent the possibility of a call. These were matters which, perhaps, ought to be dealt with at the special meeting which had been called to follow the ordinary meeting. Referring more to what had been done in the past, he had in his hand a list of the contracts, exhibitions, &c., made by the Company, and a list showing what their sales and contracts had been, and what they had expended on exhibitions. A very pertinent question was sometimes put to him by shareholders. How, when you have spent this large sum and have not made a profit, do you expect to make a profit out of fresh money? Up to the date of October, 1882, they made sales amounting to £6,776, with a clear profit on that of £1,666. These were sales of their lamps, dynamos, and apparatus—sales which had been carried through. They had had some contracts, and they would understand that these early contracts were more or less competitive, the lowest price being taken. They had had a great deal of this kind of opposition to contend with. They took a certain amount of contracts as low as they could. There was the Metropolitan Railway—a contract for which had been undertaken before this Company was formed. That, however, was part of the terms on which the shareholders subscribed their money. On that they made a loss of £1,225. Then there was the Edinburgh Post Office. At that installation they put up an engine powerful enough to do three times the amount of the work, and it was not necessary for him to explain to them that the engine and people that had to work a dynamo were just as expensive for three lights as for 300, barring the expense of coal and carbons. They provided there in the expectation of having a larger number of lamps to supply, and they made a loss of £380. The moment they could withdraw from that work they did so. They thought it well at a certain sum to take a contract for lighting the Botanic Gardens. There they had a loss of £26, while at Reading they also made a loss of £26. On the City lighting—which was also a contract on which the shareholders subscribed their money, and on which the reputation of their light had been very much sustained—they had made a loss of £4,405. That sounded bad, but how did it come about? They started with a new company. The shareholders might say, Why did you not take advantage of what you might have learnt from the Brush and other companies? Those companies, however, did not give information to their rivals, and they had found that those companies also had been unsuccessful with their cables. They in this Company had had to lay their cables two or three times. Their great loss on the City lighting had been owing to the cables and the difficulty of getting them properly to carry the electricity from the other side of the river. However, the loss there was certain loss, by which they had gained a certain amount of experience, and though they were pressed now to take another contract for the city, they might depend upon it that if it were taken it would be at a profit. At the last meeting it was said that they had not exhibited, and they replied that they could not afford to do so. They had spent no less than £1,347 for the Crystal Palace Exhibition; at Warwick House, Regent-street, £170; at the Guildhall, £160; and at the Albert Hall, £50. These were exhibitions. At the Opera House, too, there was an instaliation before this Company came into existence, and there was an expenditure of £128. Altogether £1,868 had been spent on exhibitions, and that, added to the loss of £6,064, was a very considerable item. Having, however, got all the advantage they could by the exhibitions, they had declined to exhibit any more. Some people had said "Why do you not exhibit at the Aquarium?" and they had replied, "Because we will not exhibit any more without being paid." Those were the grounds on which he thought, having paid for their experience very largely, and having plenty of contracts actually before them, and plenty more in view, and knowing exactly what they could do electric lighting for, they would be justified in asking them to carry on the Company, which he believed would yet be a great success. At the special meeting they would be able to deal with this matter, and the proposed increase of the capital.

Sir HERBERT BRUCE SANDFORD, in seconding the motion, stated that of the sum of £14,456, which figured in the balance-sheet under the head of debtors, £10,000 was due by the Lancashire Company when they had allotted more of their shares. The amount was not all due at once. The sum of £16,302 appeared as expenditure for the year, but there was £3,190 in that amount for depreciation of stock, which did not appear in the first year's expenses. There had also been an increase as compared with the previous year of £650 in the legal expenses. These two items, therefore, accounted for £4,848 of the £16,302.

Mr. TALLERMAN, at some length, complained of objection having been taken to his continued sitting on the committee which had been appointed to go into the Company's affairs.

The CHAIRMAN stated that Mr. Tallerman had not been appointed a member of the committee at the meeting of shareholders, and he therefore really thought that those who had objected, in face of that fact, to the continued sitting on the committee if Mr. Tallerman were not to blame [hear, hear]. In further reply to Mr. Tallerman, the chairman added that the British Indian Company was never floated, through the absence of the promoter, who would have helped it to float.

Mr. TALLERMAN then complained of the losses which had been made by the contracts and the purchase of patents now obsolete. However, the Company was possessed of two of the best patents, used most extensively in America, and what had they done with them? He went on to contend that the Lancashire Company had become possessed of one of the only good assets which this Company had. He also complained of the large amount which was expended in starting the Company.

After some discussion of a somewhat personal and recriminatory character,

Mr. WILLIAM ABBOTT said the shareholders ought to sink all personal differences, and proceed with the business for which they were called together. The first business was the passing of the accounts and the election of directors. If they did not pass the accounts they would not be showing much confidence in the Board; if they passed the accounts they would exonerate the directors. He did not know what were the qualifications of the managing director, but he must say he was grievously disappointed at the outcome of the business for the carrying on of which the Company was established. They seemed to have expended about £172,000 without any result to the shareholders in the way of dividend; and, under these circumstances, it did seem strange to him that the directors should come before the shareholders and ask them to water the capital by raising it to £500,000 without holding out a prospect of more successful results than in the past. Of course they must make some allowance for the rampant speculation which had taken place in the shares of electric lighting companies. He did not think that any of these companies, not even the celebrated Brush Company, had been so successful as was anticipated. It was for the shareholders to consider whether they would retain the present directors on the Board or whether they would strengthen the Board by men of experience. It was a business which required constant application and attention.

The CHAIRMAN, in reply to observations, proceeded to justify the action of the Company in bringing out the Lancashire Company. Mr. Watt, who had a large connection in Liverpool, succeeded, working with Mr. Thompson, an engineer, so far in establishing this Company's system in Liverpool, that two other companies who tried to light the district left, and this Company's system was the only system of electric lighting now going on in Liverpool. Mr. Watt asked nothing for his trouble and labour, whilst other promoters asked very large sums; but on looking over the Articles of Association the directors found they were at liberty to remunerate any officer for special service, and therefore they decided they would give Mr. Watt his qualification in the Lancashire Company, namely, 200 shares, which, however, had not been given. The Lancashire Company was floated, and it was not the directors' fault that they did not obtain the capital required, and therefore that the Lancashire Company was unable to pay the parent Company. As regarded Mr. Tallerman's interest in the Company, that gentleman had asked the directors for the concession for the Australian Colonies for himself and a syndicate.

Mr. HUGH WATT (managing director) denied that he had ever refused to give information to any shareholder. He joined the Board as one of the largest shareholders at the request of Sir Herbert Sandford. He had never received a farthing for carrying through the Liverpool Company. As regarded the expenses they compared favourably with those of the previous year, having been £16,300 last year against £16,480 in the previous year, and he might mention that a considerable portion of the expenses included in last year's accounts were incurred in the previous year. For the last three months the expenditure had been about £2,000. The profits for the last three months had been £1,400, whilst the profits for the previous eight months had been only about £200. With regard to the manufacture of lamps, when he joined the Board the Maxims were costing 17s. 6d. per lamp; they were now costing 2s. 6d. per lamp. The Weston lamps when he joined were costing £7 per lamp; they were now costing only £3. They would be able to pay expenses out of the Weston lamp alone.

Mr. DODSON and one or two other gentlemen addressed the meeting, chiefly on their personal dealings with the Company.

The report of the committee was then read. The committee expressed the opinion that the Company possessed a property which should become valuable; at the same time, they came upon much which they must unequivocally condemn. They considered that a large sum had been frittered away. For the success of the Company money was absolutely necessary, and the prospects of the business were such that the committee had no hesitation in recommending the shareholders to find the money; but there must be a great change of management. If the shareholders would not find the money several friends were prepared to find it.

The CHAIRMAN said that before proceeding further it was necessary to decide whether or not the shareholders would accept the accounts. He strongly objected to the expression in the committee's report that a large sum had been "frittered away."

The resolution for the adoption of the accounts was then put and rejected.

A suggestion was made that the meeting should be adjourned for a fortnight, in order to give time for the shareholders to consider the statements

Digitized by Google

made in the report of the committee, and also whether new directors should be appointed.

Eventually the meeting was adjourned for a fortnight, at the same time and place. The business of the special meeting was also adjourned.

REUTER'S TELEGRAM COMPANY, LIMITED.

The annual general meeting of this Company was held on the 25th inst., at the offices, Old Jewry, under the presidency of Colonel James Holland.

The SECRETARY having read the notice convening the meeting, the report of the directors was taken as read.

The CHAIRMAN then said: The second paragraph of the report, gentlemen, explains the main cause of the deficiency of profits in the past year. Our worthy secretary has just noted that this is our nineteenth ordinary general meeting, and it is, I regret to say—or rather I am glad to say it, in one sense—the only meeting at which we have had so sorry an account to show to the shareholders. The main cause of this has been the Egyptian war. So much interest was naturally taken in that war—people took such a deep interest in it—that we felt bound to have frequent and full reports of what was going on. Not only had we daily, but on many occasions hourly reports, and I think that those who bear in mind the telegraphic intelligence supplied from the seat of the war during that time will bear me out in saying that nothing could be more full, complete, or correct than the information we conveyed. But gentlemen, war is an expensive matter not only to the Government but to those whose duty it is, as in our case, to convey intelligence to the public, for we have to pay heavily for every telegram we receive and send. We, however, felt it our imperative duty, as we always must feel on occasions of interest and importance to the country, that the intelligence should be full and correct, at whatever cost, for it is the very life blood of the Company that we should be the first in the field—first and most correct. We state in the report that the telegrams alone from Egypt cost us over £3,000 more than the ordinary amount disbursed. Besides that we had to pay fully £1,000 more in the payment of special correspondents and agents engaged on our behalf to furnish the intelligence; and there were other minor charges affecting our establishment which also cost more than usual. We also had in addition to that great war in Egypt a small war of our own in South Africa, where an endeavour was made to compete with us in the furnishing of information. I have just intimated that we cannot be laggards in the race for supplying intelligence. We had to put that competition down, and we succeeded, but again the cost added very much to the other charges I have alluded to. It was very much to be regretted, but we look on these matters, and occasional heavy losses of this kind, very much as the directors of a life or fire insurance company would do. It is an actual necessity that there should be loss of life and losses involved by fire, otherwise these companies would not exist; but there will be years when extraordinary losses will come on life and fire insurance companies, and they find themselves heavily hit. The past year has been one of those years with us. There was another item that swelled the general charges. Our worthy secretary was employed on a tour of inspection in India. This was very laborious, and the travelling charges were very heavy. It was, however, a purely exceptional case, not likely to occur again for years. He did very good service, but travelling in India is a matter that cannot be done for nothing. All or most of these charges are exceptional. Unless we have fresh wars, or agitations, we may expect in future years that we shall recur to our normal state. I have mentioned—and I think without blinking in the least—the various causes which have led to the somewhat unpleasant balance-sheet before you. At the same time there is always more or less of a silver lining to every cloud, and if you refer to the figured statement you will find that the subscriptions and commissions for the year have increased by about £900, showing that our business is by no means falling off—that while the expenditure is exceptional, the source from which future profits may be drawn is progressing in a very satisfactory manner. I may also mention that the sum taken from the reserve fund to give 5 per cent. dividend is not quite so heavy as would appear on the face of the statement. We there state that £2,500 has been taken from the reserve fund. It is quite true that we did that, but in accordance with the policy we declared when we purchased the freehold of this property we have carried every year since—and we intend to do so in future—£550 in the name of rent, as it were, to the reserve fund. We did that on the present occasion, and if you deduct that amount from the £2,500 we have taken from the reserve fund, you will find that we have really withdrawn somewhat less than £2,000. As to the general figured statement, the only other matters of interest remaining to be alluded to are sundry debtors and creditors, about £15,000 on each side. All of those have fairly run off. There is nothing in them to occasion the slightest anxiety. Those against us have all been paid off, and those for us are either paid, or there are some balances in the hands of agents. To the best of our knowledge and belief we have not a single bad account. I have now given you a full and fair account of the causes which have led to the present balance-sheet being unsatisfactory, and I have only to move—"That the report and balance-sheet now presented be received, adopted, and entered upon the minutes."

Admiral Sir John C. D. HAY, Bart., M.P., having seconded the motion, it was carried unanimously.

The CHAIRMAN then moved the re-election of Admiral Sir John Hay to his seat at the Board.

Mr. STOPFORD seconded the motion, which was carried unanimously.

The retiring auditors, Messrs. Quilter, Ball, and Co., having been re-appointed,

General J. F. M. BROWNE moved, and Mr. KEENLYSIDE seconded, a vote of thanks to the chairman and directors for their services in the past year. The motion was carried unanimously.

The CHAIRMAN, in acknowledging the compliment, expressed a hope that the next meeting of the Company would be held under more favourable circumstances.

The proceedings then terminated.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).

The directors will submit the following report and accounts of the above Company for the half year ended 31st December, 1882, at the nineteenth half-yearly general meeting, to be held on the 4th May, 1883. The revenue for this period amounted to £88,408 18s.; and the working expenses (including £2,146 9s. 9d. for repairs of cable) to £14,971 5s. 2d. After providing £1,311 17s. for income-tax there remains a balance of £72,125 15s. 10d.; to this is added £1,295 4s. 4d., brought forward from 30th June last, making a total of £73,421 0s. 2d. First and second interim dividends amounting to £39,000 have been paid, and £25,000 transferred to the reserve fund, leaving the sum of £9,421 0s. 2d. to be carried to the next account. The serious fault in the Lisbon-Madeira section, referred to in the last report, was removed on the 31st October, 1882; it had evidently been caused by the breaking of the wires by a ship's anchor; the fresh cable spliced in is now in closer proximity to shallow water, therefore less liable to be injured by vessels anchoring. The new cable between Lisbon and Madeira was successfully completed on the 19th October, 1882, by the Telegraph Construction and Maintenance Company, thus duplicating the first section of this Company's system. All the Company's cables are in good working order. The directors have appointed Mr. Carlos Frederico Taylor their representative in Brazil, in accordance with Article 27 of the Concession.

SLIP

ELECTRIC LIGHTING AT NORWICH.—The experimental lighting of certain parts of Norwich by electric lamps is to be discontinued for the present.

ELECTRIC LIGHTING AND THE ISLINGTON VESTRY.—This Vestry have resolved to call in an "expert" to advise them in electric lighting matters.

RESIGNATIONS.—It is stated that Mr. Cordner, general manager, and Mr. Allen, chief electrician, of the Anglo-American Brush Company have resigned their respective posts.

SOUTH AFRICAN CABLE AGAIN INTERRUPTED.—The Eastern Telegraph Company announce that the Eastern and South African Telegraph Company's Mozambique-Zanzibar cable is again interrupted.

ELECTRIC LIGHTING FOR SYDENHAM.—The Brush Company have applied to the Lewisham Board of Works for permission to light a portion of Sydenham near Kirkdale. The Board have referred the matter to their Works Committee.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.—It is notified by the Telegraph Construction and Maintenance Company (Limited) that a distribution of 1s. per £5 certificate will be made on the certificates issued under the Trust Deed of 1875.

ELECTRIC LIGHTING IN THEATRES.—The Société Electrique Edison, of Paris, have, we are informed by our Austrian correspondent, got an order to light the new National Theatre at Prague by their system. About 1,700 A (16 candle-power) lamps will be required.

LONDON AND GLOBE TELEPHONE COMPANY.—This company announce the establishment of a Metropolitan Telephone Exchange, the subscription being £10 10s. per annum. They also intend fixing automatic fire alarms in warehouses and private houses.

THE BRUSH SYSTEM IN MEXICO.—It is stated that arrangements have been made with the authorities in the city of Mexico to light the town and its suburbs on the Brush system by a private company formed for that purpose by influential houses in London and Mexico.

THE TELEPHONE IN THE PROVINCES.—A provincial paper says that Messrs. J. and W. Maxwell and Sons, of the Silloth Chemical and Manure Works, are about to establish telephonic communication between the works and their office in Carlisle. The wire will be fitted on the existing telegraph posts..

COUPON DUE.—The Eastern Extension, Australasia, and China Telegraph Company (Limited) have given notice that the coupon on their Five per Cent. Manila Debentures, due on the 1st inst., will be paid at the Consolidated Bank, 52, Threadneedle-street, E.C. Coupons should be left three clear days for examination.

ELECTRIC LIGHTING AT LEEDS.—The Town Council, at their meeting on Wednesday, voted a sum of £10,000 for the purpose of applying the electric light to the Town Hall, the new municipal offices, and a few of the principal streets in the borough, preparatory to the general application of the light if the experiment proves satisfactory.

WRECK OF A CABLE STEAMER.—A Lloyd's telegram received from New York states that the steamer Professor Morse, 1,023 tons, employed in telegraph cable laying, whilst on a voyage from New York to Boston, ran ashore on Block Island, Rhode Island, and is full of water. The vessel has been abandoned, it being found impossible to save her.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of April was 4,411, estimated to produce £3,900, against 3,937 messages, producing £3,921, in the corresponding month of last year. The traffic receipts for the month of January, estimated at £2,800, realised £2,829.

AN ELECTRIC RAILWAY AT WIMBLEDON.—The National Rifle Association have entered into a contract with the Electric Motor Syndicate to lay down an electric railway at Wimbledon on their improved system, and to work it during the meeting of the association in July next. The train will consist of six carriages, carrying twenty-four passengers each.

ELECTRICITY AS A MOTIVE POWER.—This was the title of an interesting paper by Professor George Forbes, which was read at a meeting of the Society of Arts on Wednesday last, Mr. W. H. Preece occupying the chair. We regret that the amount of matter awaiting insertion in the two last numbers of the present volume will necessitate our keeping Professor Forbes's paper for the first number of Vol. XI.

ELECTRIC LIGHTING IN BRUNN (AUSTRIA).—The Edison Company are going to light up a second factory in Brünn by their system. Some 250 lamps will be used. We learn that the lamp factory started in this town by Mr. Francis Jehl is so far ready for work that the first Edison lamp was completed a few days ago. The lamps on the stage of the theatre have now burnt for over 1,500 hours since the opening ceremony.

SOCIETY OF TELEGRAPH ENGINEERS.—At the meeting of the society to be held at 25, Great George-street, at 8 p.m. on Thursday, the 10th May, the following papers will be read:—"The Electric Holophote Course Indicator, for the Prevention of Collision at Sea," by J. H. A. MacDonald, Q.C., Associate; "Electro-Motors and their Government," by Professors W. E. Ayrton, F.R.S., and John Perry, Members.

THREATENING A POSTAL TELEGRAPH OFFICER.—At the Guildhall, on Wednesday, James Bastaple, of Hart-street, Covent-garden, W.C., was committed for trial for sending a letter to Mr. Fleetwood, inspector of underground telegraph wires, in which he threatened to kill both the inspector and a foreman of works. It appeared that the prisoner had been dismissed the service by Mr. Fleetwood, and that he considered his dismissal was due to the foreman of works.

ELECTRIC LIGHTING AT CHESTERFIELD.—At a recent meeting of the Chesterfield and Derbyshire Engineers, held at Chesterfield, two papers on electric lighting were contributed. In the course of a discussion on one of these papers a member remarked that he "nearly fell over the lamps (now in use at Chesterfield) in trying to find them," from which it is to be presumed either that the gentleman in question is remarkably shortsighted or that the lamps do not give much light.

DUBLIN TELEGRAPH CLERKS.—In the House of Commons on Thursday week Mr. O'Donnell asked the Postmaster-General why the female telegraph clerks at Dublin, receiving 30s. a week and upwards, were refused the annual holiday of three weeks enjoyed by female telegraph clerks receiving similar rates of salary in London. Mr. Fawcett replied that the difference between the annual periods of leave in London and in Dublin appeared to him to be an anomaly, and that he would see whether steps could not be taken with a view to its removal.

TO BE WOUND UP.—The petition for the winding-up of the Electric Light Syndicate was heard by Mr. Justice Fry on the 20th April, and an order for winding-up made.—The Scandinavian Electric Company, of 20, Bucklersbury, E.C.,

Digitized by Google

is to be wound up, voluntarily.—The Plating Company, of 34, Kirby-street, Hatton-garden, E.C., is also to be wound up voluntarily.—A petition for the winding-up of the British and Irish Telephone and Electric Works Company, presented by John Gaskell, a creditor, is to be heard before Mr. Justice Pearson on the 11th instant.

The Vienna Exhibition.—We are informed that the organising committee of this exhibition have made arrangements with Herr A. Hartleben, publisher, of Vienna, to collect for them as many works dealing with electricity and its applications as possible, also all the periodicals of the day connected with electrical science and practice. These will be exhibited in a special room, where they can be consulted free. In fact, a reading room will be provided, the contents of which will be of an international character. Electric lights only will be used in this room.

Chess-playing by Telephone.—Several games of chess have lately been played in provincial towns, notably Leeds and Bradford, in which the moves were announced to the respective players by means of the telephone, the players occupying different houses at some distance from each other. The latest example of this mode of chess-playing took place at Scarborough a few days since, between two shops belonging to Messrs. F. Wallis and Son, in Newborough and South street respectively. The instruments used were the Gower-Bell, the line having been put up for Messrs. Wallis by the Post Office officials.

The Model Provisional Order.—In the House of Commons, on Friday week, Mr. Chamberlain told Mr. Yorke that several local authorities in the metropolis were anxious for an extension of time for considering the Model Provisional Order of the Board of Trade; but he found that any such extension, if granted, would render the provisional order impossible during the present Session, owing to the Standing Orders of the other House. Many of the principal authorities in London and the country had already come to a satisfactory arrangement, and, in his opinion, all of the bodies had had ample time for the consideration of the subject.

Electric Lighting and the Board of Trade.—The Greenock Town Council sent a deputation to wait upon Mr. Chamberlain the other day to urge the necessity of amending the permissive powers of local authorities as to electric lighting, or, at all events, to extend the time allowed for experiments within a compulsory area from two to five years. Mr. Chamberlain being otherwise engaged when the deputation called at the Board of Trade, they saw Mr. T. H. Farrer, permanent secretary. This gentleman promised that the matter should receive attention, but did not think that there was any hope of the period during which experiments could be made being extended.

Charing-cross Electric Railway.—When the Select Committee of the House of Commons, presided over by Admiral Egerton, met on Tuesday, for the purpose of inquiring into the merits of the Charing-cross and Waterloo Electric Railway Bill, it was announced, on behalf of the promoters, that it was their intention to withdraw the Bill for the present Session. The withdrawal of this Bill will not, however, interfere with the construction of the first section of the above line, viz., that between Charing-cross and Waterloo. The Bill which has been withdrawn related to the extension from Waterloo to the neighbourhood of Queen-street, crossing under the Thames again at Bankside.

Electric Lighting in the Holborn District.—At the last meeting of the Holborn District Board of Works a report was received from the Board's Committee of Works reporting on the application of the Metropolitan Brush Company, and recommending, after conferring with the representatives of the company, that on the company including the parish of St. Sepulchre, Middlesex, within schedule A of the area of supply, also furnishing a map showing the whole of such area, and appropriating a sum of not less than £15,000 as a capital, the provisional order be agreed upon in the model form settled by the Board of Trade. A letter was also received from the company, confirming the agreement come to with the committee as to including St. Sepulchre in schedule A and the remainder of the district in schedule B. The committee's report was adopted.

Joint Stock Companies.—According to a notice in the *London Gazette* for May 1 the undermentioned have been struck off the Register of Joint Stock Companies:—Allan's Trans-Atlantic Telegraph Company, Economic Telegraph Company, Finsbury Telegraph Newspaper Company, Great Northern Electric Light Company, Oriental Telegraph Company. The following will be struck off the register at the end of three months from May 1, unless cause is shown to the contrary:—Anglo-Danish and Russian Telegraph Company, Anglo-Indian Telegraph Company, Danish, Norwegian, English Telegraph Company, Direct English, Indian, and Australian Submarine Telegraph Company, Electro-Protector Boiler Company, Franco-American Telegraph Company, Provincial and Foreign Telegraphic News Company, Telegraph Works Company, West Indian and American Telegraph Company.

Sixpenny Telegrams.—In the House of Commons on Thursday week Mr. Dawnay asked the Postmaster-General, in view of the proposed alteration with regard to 6d. rates for telegrams, an alteration which it is computed will entail a loss of £170,000 a year, what arrangements would be made in the case of the rural post offices, where contracts had been signed under which the shillings at present paid in for telegrams were allowed to the guarantors of the annual sum paid to the Post Office Department; and whether the guarantors of such sums would be secured from any share in the loss which it was calculated would be entailed on the revenues of the Department by the change in the telegraphic rates. Mr. Fawcett replied that he thought it would be only fair that guarantors should not suffer any pecuniary loss from the proposed reduction of telegraphic charges, and they would not, therefore, be called upon to pay any more than the payment made in the last year or the average payment of the three last years.

Gas in Paris.—Paris and its light purveyors have been quarrelling. "Paris is threatened with a plague of darkness," telegraphed the correspondent of a daily paper a day or two ago, and continued, "The misunderstanding between the city authorities and the gas company has reached such a pitch that the latter declares, unless the old price of 15c. per cubic metre be maintained, it will cut off the supply on Friday next (May 4). A Prefectoral decree of March 22 enjoined the company to reduce the price of gas for lighting the city from 15c. to 12½c., and of that supplied to private consumers from 30c. to 25c. The company denied the right of the Municipal Council to order a reduction in the price, and instituted legal proceedings against the city, which have not yet been brought before a court of law. Pending a decision, private individuals will continue to pay the old price, but the city government adheres to its intention of only paying 1¼d. instead of 1½d. Unless, therefore, the company give way, it will close the meters on Friday, and the gasworks will, in accordance with a clause in the agreement, be taken over by the city. As so important a transfer can, however, scarcely

Digitized by Google

be effected in a day, there is a possibility that Paris, during Friday night at least, will be plunged into utter darkness, to the delight of malefactors generally, and terror of honest folk. Such are the benefits of huge monopolies."

Long Distance Telephone Company.—The prospectus of a company that has been formed under this title has appeared in the advertisement columns of the daily papers for the last few days. The capital is put at £600,000. The company will work the patents of Mr. Hopkins, an American electrician. Before subscribing to this company it would be well to ask the promoters, "Have you a license from the Postmaster-General?" The answer to this question should be insisted on, as without such a license all the patents in the world are no use, for the simple reason that they cannot be used. The prospectus gives elaborate estimates for the erection of trunk lines to Liverpool, Manchester, and other large towns. Now, seeing that the Postmaster-General alone has the power to erect such lines, it is taking time a little too forcibly by the forelock to publish estimates like those above-mentioned before obtaining a license from the Postmaster-General. We notice that the United Telephone Company have challenged the validity of the Hopkins patents, and it seems likely that the saying, "Who buys a telephone, buys a lawsuit," will be exemplified should the company get their money and endeavour to sell their telephones. We have given our opinion upon the long distance trials in America in a previous note. Since writing the above, we notice that the United Telephone Company have proceeded against the Long Distance Company, and that Mr. Justice Chitty gave leave to serve a short notice of motion for an injunction on Friday.

The Brush System in Aberdeen.—The experimental lighting on the Brush system has come to an end, and the following report on the cost, &c., given in by the Gas and Lighting Committee of the Town Council:—"We beg to report that the time granted by the town council for the experiment in electric lighting presently being carried out by the council is now expired. The experiment was commenced on the 23rd day of December last, and has been carried on with little or no interruption since. Everything in connection with the experiment has been as economically carried out as possible, and the cost of the whole will be as follows: The construction of plant, including the sum of £60 for taking down the apparatus and reconstructing the buildings, will be £186 14s. 9d.; maintenance and wages, including the Brush Company's charge for sixteen arc lamps, each burning on an average six hours and a half per day for 121 days, at 1¼d. per lamp per hour, £222 19s. 3d. Total, £409 14s. The amount arising from a number of the gas lamps not being lighted, as per a report from the Inspector of Lighting, is £34 11s.; reducing the maintenance to £188 8s. 3d., and the whole expenditure in connection with the experiment to £375 3s. The sixteen electric arc lamps took the place of one Sugg lamp, consuming thirty cubic feet per hour; two Bray lamps, each burning fourteen cubic feet per hour; one Wigham lamp, burning twenty cubic feet per hour; and 102 ordinary lamps, each consuming two cubic feet per hour. To light the area with the electric light cost £222 19s. 3d.; ditto with gas, £34 11s.; or about six and half times more by electricity. The committee instructed Mr. Smith to take down and return the apparatus."

The Telephone in Brooklyn (New York).—In no place probably has the use of the telephone become more general than in Brooklyn. The business is now under the control of the Long Island Telephone Company, which has done as much during the past six or eight months as it did during all the previous period of its existence. The large and rapid increase of wires on our principal thoroughfares has marked the progress made in the extension of the service. "We have doubled our subscription list since last July," said General Superintendent W. D. Sargent the other day. "We then had 800 subscribers; we now have 1,600. We have extended our lines to Flushing, College Point, Whitestone, and Bayside. We are building lines to Jamaica, Far Rockaway, Hempstead, Babylon, and Patchogue, and we expect ultimately, probably during the summer season, to reach to the other end of the island. We have opened a pay station at Coney Island and will have stations in all the leading hotels on the beach. In the city we have rebuilt lines with first class poles, notably on Washington-street, and in the past six months have added between 500 and 600 miles of wire. About 5,000 messages pass over the wires daily in this city, and between Brooklyn and New York the number is some 30,000 a month. We have established a connection with Fire Department Head-quarters in Jay-street, so that an alarm of fire in the house or business place of any of our subscribers can be sent at once to head-quarters. We have sent many such alarms, and Commissioner Partridge in his late quarterly report to the Mayor bears testimony to the value of this arrangement. So you see we are making rapid progress. A great change has taken place since the latter part of 1881, when the company had only 101 instruments in use."—*Brooklyn Daily Eagle.*

The Bursting of Armatures.—The bursting of the armature of a dynamo, as recently reported in the daily papers, has caused much comment as to the possible danger arising from accidents of this kind, and, as usual, conclusions have been arrived at without any inquiry being made as to the facts of the case. Knowing that there is danger from flying fragments when a rapidly revolving mass is disrupted, and recalling the damage done by flywheels and grindstones, the writers guess that the effects produced by armatures acting similarly would be equally disastrous. In some classes of dynamos the armature consists of a shaft, upon which are placed many hundreds of discs of iron separated by paper, and around which coils of copper wire are wound longitudinally. Upon revolving this the centrifugal force tends to throw the copper wire off, but to hold it in place strands of spring brass wire or piano wire are bound at intervals about it. These confining bands have to resist the weight of copper only, the tensile strength of the discs being ample so far as they are concerned. Taking the diameter of the armature as twelve inches, and the speed as 1,000 revolutions per minute, each pound on the circumference would exert a force of about 169 pounds. The aggregate number of pounds of copper on the surface would cause a strain to be resisted by the combined strength of the copper wire itself and the confining bands. The difference is sufficient for a large margin of safety. When the armature is made of cast iron the tensile strength of the iron will resist the centrifugal force if the casting be without flaw, and the high degree of perfection to which casting is brought at the present time makes this aspect of the question hardly worth considering. The armature first considered is so incased by massive field magnets, and the fragments would be so light in comparison that but little danger would menace either life or property in case of rupture.—*Scientific American.*

A Firedamp Indicator.—In a letter to a recent issue of *The Times*, Mr. W. F. Howard, of Chesterfield, gives some account of a new firedamp indicator, which is interesting. He says:—"Another invention (Libin's firedamp and escaped gas indicator) has within the past fortnight and for

Digitized by Google

the first time in this country been subjected to trial at Chesterfield by myself in concert with Mr. C. E. Jones, of the Chesterfield Gas Works. The result showed that, compared with the Davy safety lamp, still almost universally used in searching for firedamp in mines, the Libin indicator denotes a less per centage either of manufactured gas or of firedamp than the lamp. This was proved first by exact and thoroughly diffused mixtures of ordinary lighting gas with air, 3 per cent. scarcely showing in the lamp, but being indicated with perfect distinctness by the Libin instrument, a 2 per cent. similar mixture being also indicated by the latter only. On further trial in a coal mine at Boythorpe, the lamp showed firedamp in one only of three places, in all of which the Libin instrument indicated its presence. The instrument as used in the mine on this occasion was connected with a small electric battery carried in a waist belt, and connected by wires with a bell; by a sliding contact arrangement no spark was given off. In this form it can be employed for examining any place in a mine that can be examined with a safety lamp. For positions in which it can be permanently fixed, it is designed to communicate and keep up intelligence of the state of the main return airways to the manager's office. In both forms, fixed and portable, but chiefly in the former, there are wide fields for its use elsewhere than in mines, particularly for the detection of gas in coal bunkers on board ship, and in buildings. On board ship, especially at different points among the cargo, where safety lamps cannot be introduced, the automatic registration of several Libin's detectors, each having a separate wire and indicator, and employed either separately or together with similarly equipped thermometers, would denote the place, degree, and extent of danger. Such warnings would, of course, suggest means of remedy in each particular instance, and ultimately, it may be expected, would lead to better methods of stowing and insure safety."

Resistance of the Electric Arc.—Messrs. Ayrton and Perry have recently made some experiments with the object of obtaining further information as to the resistance offered by the electric arc, to supplement the data obtained by the late Mr. Schwendler in his 1878 experiments. The latter gentleman came to the conclusion that the supposition that the resistance of an arc of constant length was inversely proportional to the current which passed through it was highly probable. Messrs. Ayrton and Perry's first series of experiments were made with Grove cells, so arranged that 30, 40, or 50 could be thrown in or out of circuit, so as to increase or decrease the current without any interruption. An ammeter was placed between the cells and one of the carbons, and a voltmeter between the two carbons, so as to measure the current going through the arc, and the difference of potential between the carbons. The position of the arc was adjusted to a fixed distance, and the experimenters managed to take three readings before the light went out. The following are the results:—30 cells gave a current of 6·52 amperes, a difference of potential between the carbons of 30·4 volts, and the work in foot-pounds per second in the arc amounted to 146·2. With 40 cells the current became 10·16, the difference of potential 30·4, and the work 227·8. With 50 cells the current was 11·92, the difference of potential still remaining steady at 30·4 volts, whilst the work increased to 267·2 foot pounds per second. Subsequent experiments were made with a Brush dynamo, readings of the voltmeter only being taken, and the current being alternately trebled and diminished to one third by the alteration of resistances in circuit. From the readings obtained it appeared that for a fixed distance between the carbons the difference of potentials necessary to maintain the arc is nearly but not quite independent of the current, the electromotive force requiring to be slightly increased when the current is very much increased. The next question was to ascertain in what way the differences of potentials between the carbons varied with the length of the arc when the current was kept constant. The mode of procedure adopted was to fix on a particular current for each set of experiments. The carbons were then put successively at different distances apart, and the resistance in the circuit varied until the pre-arranged current was flowing through the arc, when instantly the arc was projected on a screen by a lens of known magnifying power, and the actual projected distance between the carbons on the screen read off, and the difference of potentials between the carbons ascertained. A number of experiments were made in this way with a Brush machine for currents varying between 5·5 and 10·4 amperes, the distances between the carbon points from 0 to one-and-a-quarter inch, and the difference of potential varying from 0 to 140 volts, the carbons being ·24 inch thick. The result showed that at first the difference of potentials necessary to maintain the arc increased rapidly with the distance, and that at a distance of about one-tenth of an inch it was about 60 volts. This increase continued up to one quarter of an inch distance, after which the difference of potentials necessary became nearly proportional to the increase of distance, being about 54 volts per inch increase. The experimenters plotted these results, and obtained a curve for the increase very like that obtained by Mr. C. F. Varley for the discharge through a vacuum tube, and, Drs. W. de la Rue and Hugo Müller for the connection between the electromotive force, and the distance across which it would send a spark. The result of the experiments showed that the difference of potentials between two carbons necessary to produce an arc depends almost entirely on the distance between them, and hardly at all on the strength of the current. A detailed account of these experiments will be found in the *Philosophical Magazine* for May. Messrs. Ayrton and Perry conclude by expressing their opinion that "in all probability the conduction from particle to particle in a microphone is of the nature of a small electric arc, or rather perhaps a convective discharge."

Prospects of Electric Lighting. — An interesting lecture under this title was delivered by Mr. T. P. Barkas to the Tyneside Students' Association, in the rooms of the Newcastle-on-Tyne Literary and Philosophical Society, on Thursday, April 26. The lecturer began by tracing the history of electrical science from the time of Thales, of Miletus, to the present day. "Electricity during the present century," said Mr. Barkas, "has revolutionised our conceptions of the powers and possibilities of nature, and has transformed the earth into a fairy palace, more wonderful than the palace of Aladdin, with all the properties of his wonderful lamp." And yet how far we are from any complete conception of what electricity really is. Notwithstanding the strides that have recently been made in electrical science, we may say with Byron in his "Manfred,"

> Science
> Is but an exchange of ignorance for that
> Which is another kind of ignorance.

Mr. Barkas then proceeded to give some account of the earlier forms of arc and incandescent lamps, such as Staite's, King's, and Starr's (all of which have been illustrated in our pages within the last year or so), and their successors, together with the dynamos that have been invented, and have enabled the electric light to enter

Digitized by Google

into competition to a certain extent with gas. It was the want of these dynamos, the lecturer pointed out, which had caused the earlier experimenters in electric lighting to give the matter up as impracticable, although gas at that time had only just been introduced, and was of very bad quality. He then briefly alluded to the great improvements that were successively introduced into the manufacture of gas, and how this means of illumination had advanced in public favour, mentioning, *en passant*, that five years ago Newcastle £100 gas shares sold for £110, whereas a few days ago they were sold in large quantities at £160. He contrasted this with Brush £10 fully paid shares, which not long ago sold for £56, but were now unsaleable at £8. The lecturer then explained the electric units now in use and their values. Passing on to consider arc and incandescent lamps, he explained that all forms of metallic incandescent lamps have given place to carbon lamps, notwithstanding the fact that metal is more easily raised to incandescence, because the former are more easily fused, and also because the resistance of metals increases with heat, whilst that of carbon filaments decreases. To illustrate this he gave some figures relating to various incandescent lamps, showing their resistances when cold and hot. According to Mr. Barkas, Maxim lamps have a resistance of 70 ohms cold, and 35 ohms hot. Swan lamps are 70 ohms cold and 30 ohms hot, Edison lamps are 250 ohms cold and 125 ohms hot, and Lane-Fox lamps 70 ohms cold and 38 ohms hot. The secondary battery the lecturer traced from the experiments of Gautherot, in 1801, to Planté and Faure at the present day. "Theoretically," he said, "secondary batteries appear to be very efficient—that is, they ought to store E.M.F. put into them, but practically, from obstacles of various kinds, they do not. There are many practical difficulties in the details of working secondary batteries, and I have seen long rows of Faure batteries, sufficient, if in proper order, to light a theatre with 1,000 lamps, unable to light a few lamps in a shop, because of some undiscoverable errors in their arrangement, or some unexplained or undiscovered local discharge." Mr. Barkas concluded by giving an account of the electric light mania of three years ago, and the feverish way in which shares in the companies then floated were snapped up, contrasting the high price paid for those shares with the discount at which many now stand. From this comparison he drew his own conclusions, which were that the outlook for electric lighting was a gloomy one. Here we are at variance with Mr. Barkas. The mania of the past few years is coming fast to its legitimate end, many companies then started have already been wound up, more are in process of being wound up, and there are probably more to follow. Thus a much-desired clearance is being effected, which will leave room for those who do know something of electric lighting, and have some right to the title, "electric light engineers." We think that Mr. Barkas will change his opinion as to the future of electric lighting before many more years have passed over his head, though we have no doubt that a great deal of the money so rashly subscribed by the public, to the great benefit of company promoters, will be lost.

Repairing Cables off Sicily.—We make the following extract from the *Gazzetta di Messina* of the 28th March:—"On the 21st inst. the operations undertaken by the English steamer 'Volta,' belonging to the Eastern Telegraph Company, under the command of Captain Pattison, with the object of repairing the cables between Sicily and the main land, were brought to a satisfactory conclusion. A new cable consisting of three wires was laid, and another which had ceased to act was taken up and repaired. The Italian Telegraphic Administration, for whom the aforesaid operations were carried out, was represented by the Inspector-General of Telegraphs, Commendatore Signor Clemente Viale, whilst the Eastern Telegraph Company was represented by its own superintendent, Chevalier Eggington, the electrical tests and experiments being entrusted, as far as they concerned the above-mentioned company, to their electrical engineer, Mr. James Anderson. The Eastern Telegraph Company, whose network of submarine cables stretches over such a vast extent of our globe, reaching to the most distant seas, is possessed of ways and means in proportion to the vastness of its undertakings. The company is the owner of several vessels specially fitted up with the necessary apparatus for carrying out undertakings of this description. The 'Volta,' whose name is a glorious one in Italy, is one of the finest and newest of these vessels. Those who have had the pleasure of visiting this model ship cannot but have admired the way in which everything that science can devise as the most useful and the newest in the way of submarine telegraphic appliances is to be found on board—from huge and powerful steam engines for sinking and taking up submarine cables to the most delicate instruments for testing the electric condition of the same. Besides all this, she has on board every description of nautical instrument, and is fitted up with everything that is conducive to comfort in the way of tasteful and elegant decorations and other arrangements. Another point which renders this vessel specially worthy of notice is that the lighting of the saloon, of the passages, of the cabins reserved for the captain and his officers, is effected by Swan lamps. It is a pleasant light, having a rosy and mellow tint, and distributed through a proportionate number of lamps. It is not a dazzling light, nor such a light as is generally used in illuminating a public square, but a light suitable for a saloon or sitting room. On the bridge there is a 'Rechercher,' or search light of capacity sufficient to light up with the clearness of noon-day the decks of the vessel and her neighbourhood for a radius of one kilometre. This apparatus is most useful in the work to be done, and for the safety of the ship. In conclusion, everything is so well arranged on board the vessel, that whoever visits her cannot fail to come away delighted. The good impression made on any one visiting the vessel is completed by her worthy commander, Captain Pattison, who is the model of a seaman. His build is of the Herculean order, but he has, withal, an expression of kindliness and good nature, coupled with a dignified mien, which makes him a favourite at once. In fact, in his case, outward appearance is a sure index to a true and kindly heart. As a proof of this we may state that on the 21st inst., whilst he was carrying out his operations in connection with the submarine cables, he came upon the fishing smack called 'Due Fratelli,' which had run aground on Pezzo Point, near Cannitello, and was in a desperate plight, the seas making a clean breach over her. Captain Pattison at once and unasked tendered her his help, set her afloat again by means of his engines, and rescued her from her perilous position. Subsequently he fell in with another sailing vessel which had also run aground, was without any boats, and had her bowsprit damaged. To her also he offered his services, and would have rendered them to her had not her captain some short time previously telegraphed for a tug to tow her into the harbour of Reggio. At this time the weather was stormy, and a heavy gale was blowing from the west. Such services rendered at a time when Captain Pattison was performing a most important and delicate task undoubtedly show that he has the generous heart and the intrepidity of a true seaman."

SOME ELECTROSTATIC AND MAGNETIC RELATIONS.

BY OLIVER HEAVISIDE.

(CONCLUDED FROM PAGE 559.)

9. The division of physical magnitudes by Hamilton into scalars and vectors is not merely one of the most useful ideas ever conceived, but is also one that is perfectly intelligible to every one as a natural division. Scalars being such as pressure, temperature, density, and so forth, directionless, and requiring but one specification, viz., magnitude; and vectors being such as displacement, velocity, force, &c., involving direction as well as magnitude, and, therefore, requiring three specifications (as the magnitudes of the components in three rectangular directions; or the magnitude of the vector itself, and two data to specify its direction), it is impossible to confound scalars with vectors. They are distinct and separate entities. The word entity is obviously applicable to a scalar, whilst it is equally applicable to a vector in spite of its three data. The data may be of different kinds, yet the final result is the same, viz., a definite directed magnitude.

But although we cannot combine a scalar with a vector to form a fresh scalar or fresh vector, or a new quantity having an individuality of its own, it is sometimes convenient to pair them, and the result is called a quaternion, the name implying the four data. But a quaternion is always merely a definite scalar and a definite vector paired, and is consequently a purely artificial idea, not having the same naturalness as a scalar or a vector. A and C are thus quaternions, whilst Z, B, and D are pure vectors. Nevertheless, so far as the potential property goes, there is no occasion to draw any distinction between them, for we have Z = potential B, A = potential C, and B = potential D. [In the quaternion analysis, however, a quaternion assumes more definiteness than in the above, being in fact the ratio of two vectors, *i.e.*, the operation that must be performed upon one vector α to turn it into another β. Imagining them drawn from the same point, we may turn α into β by first rotating α through a definite angle in their common plane until it coincides with β in direction, and then by stretching or shortening it till it is identically the same as β. The angle of rotation and the stretching require each one specification, and the plane of rotation two more, thus making four in all.]

10. In the next place we may notice that the energy properties of Z, A, B, C, and D with the suffix 1 have their parallel in the other set with the suffix 2. We have already discussed the former, relating to the current system, and shown that

$$\Sigma B_1^2 = \Sigma \overline{A_1 C_1} = \Sigma \overline{Z_1 D_1} = \ldots \quad . \; . \; (\alpha),$$

the summations extending over all space. ("Current Energy," III. and IV., p. 390 and 437 *ante*.) Now in the other set we have exactly similar relations amongst the mixed scalars and vectors, viz.:

$$\Sigma B_2^2 = \Sigma A_2 C_2 = \Sigma \overline{Z_2 D_2} = \ldots \quad . \; . \; (\beta).$$

In equation (α) the quantities are all vectors, and the stroke indicates that the product of the numerical values of the two vectors concerned is to be multiplied by the cosine of the angle between their directions. In (β) the stroke appears in the third summation, because Z_2 and D_2 are vectors, but not in the second, because A_2 and C_2 are scalars, and their product is found by ordinary arithmetic.

We may prove the identity $\Sigma B_2^2 = \Sigma A_2 C_2$ in a manner somewhat similar to that employed before in proving $\Sigma B_1^2 = \Sigma \overline{A_1 C_1}$; but the process is now somewhat simpler, owing to the simpler nature of the system of force due to a charge at a point, viz., straight lines radiating equably from the charge, as compared with the closed lines of force of a current.

We have $A_2 = \Sigma \frac{C_2}{4\pi r}$, $B_2 = -\nabla A_2$, and $C_2 = \text{div. } B_2$.

Select any small volume containing the charge C'_2, say, and consider the portion of $\Sigma A_2 C_2$ belonging thereto, viz., $A_2 C'_2$. Here we have

$$\left.\begin{aligned} A_2 &= \text{line-integral of } B_2 \text{ from } \infty \text{ to } C'_2. \\ C'_2 &= \text{surface-integral of } B'_2 \text{ over a surface enclosing } C'_2 \end{aligned}\right\}$$

where B'_2 is the force corresponding to C'_2. The first of these equations follows from the relation $B_2 = -\nabla A_2$, and the second from $C'_2 = \text{div. } B'_2$. Noticing here that any path from infinity terminating at C'_2 will do for the line-integration, and any surface surrounding C'_2 for the other, and that by expanding the surface, starting at C'_2, we may make it sweep over all space, at the same time that its point of intersection by the line chosen for the line-integral goes from C'_2 to ∞, we see that $A_2 A'_2 = \Sigma \overline{B_2 B'_2}$, over all space. Similarly, $A_2 C''_2 = \Sigma \overline{B_2 B''_2}$, if C''_2 be the charge in another small volume. Hence, by including the whole of C_2 we obtain

$$\Sigma A_2 C_2 = \Sigma (\overline{B_2 B'_2} + \overline{B_2 B''_2} + \ldots) = \Sigma \overline{B_2 B_2} = \Sigma B_2^2,$$

since B_2 is the vector sum of B'_2, B''_2, &c. Interpreted for electrostatics, C_2 being density of electricity, A_2 its potential, B_2 the force, the quantity ΣB_2^2 is double the electrostatic energy expressed in terms of the square of the force throughout the whole dielectric with unit capacity, whilst in the equivalent form $\Sigma A_2 C_2$ it is expressed in terms of the charges and their potentials. It, $\left(\frac{1}{2}\Sigma B_2^2\right)$, is the amount of work expended in setting up the state of electrification, and given out again when the charges are allowed to combine and neutralise by conducting paths, in the form of heat ultimately. We must not, however, hastily conclude that $\frac{1}{2}\Sigma B_2^2$, when B_2 stands for the magnetic force of a permanent magnet, really represents the energy of the magnetisation, a matter we shall not here touch upon.

11. The other identity $\Sigma A_2 C_2 = \Sigma \overline{Z_2 D_2}$, where Z_2 is the v.-potential of B_2, and B_2 that of D_2, may be thus established. Let F, G, H be the components of Z_2 and F_1, G_1, H_1 those of D_2. Then, because $A_2 = \text{div. } Z_2$, we have

$$\Sigma A_2 C_2 = \iiint C_2 \left(\frac{dF}{dx} + \frac{dG}{dy} + \frac{dH}{dz}\right) dV,$$

and, by integration "by parts" through all space,

$$= -\iiint \left(F \frac{dC_2}{dx} + G \frac{dC_2}{dy} + H \frac{dC_2}{dz}\right) dV.$$

But $-\frac{dC_2}{dx} = F_1$, &c., since $-\nabla C_2 = D_2$; hence

$$\Sigma A_2 C_2 = \iiint (FF_1 + GG_1 + HH_1)\, dV = \Sigma \overline{Z_2 D_2}$$

in our notation.

12. We saw in Article IV., "Current Energy," that the division of the arbitrary magnetic force B into two fields, B_1 and B_2, the first due to current, the second to magnetism, is effected in such a manner that

$$\Sigma B^2 = \Sigma B_1^2 + \Sigma B_2^2,$$

the products of B_1 and B_2 completely annulling. We now see that the fields thus obtained have precisely the same energy properties, employing the corresponding connected functions in each case, without the necessity of distinguishing between the different natures of the functions.

We shall, of course, find the same relations in the quantities Z and D, since they are similar to B, being pure vectors, of which Z_1 and D_1 are the closed tube portions, and Z_2 and D_2 the open. Thus

$$\Sigma Z^2 = \Sigma Z_1^2 + \Sigma Z_2^2, \text{ and } \Sigma D^2 = \Sigma D_1^2 + \Sigma D_2^2.$$

But we cannot expect to find this property when we take the intermediates A and C, which are not pure vectors. For instance, we must not expect to have $\Sigma C^2 = \Sigma C_1^2 + \Sigma C_2^2$, for this would involve v. $\Sigma C_1 C_2 = 0$. This is a vector summation, for, C_1 being vector and C_2 scalar, $C_1 C_2$ in the summation represents a vector of length $C_1 C_2$ in the direction of C_1.

Digitized by Google

13. But although v. ΣC_1C_2 does not in general vanish, yet we have $\Sigma C_2 = 0$ and v. $\Sigma C_1 = 0$ separately. The former we have assumed from the beginning, for it merely expresses that there is just as much positive as negative magnetism, which is always the case in any arbitrarily assumed state of magnetisation. The same is true for electricity, but we must exclude lines of force going out to infinity without returning, or we may terminate such lines upon a surface enclosing the whole space considered. In fact, $\Sigma C_2 = 0$ separately for every tube of force.

The other equation, v. $\Sigma C_1 = 0$, interpreted for current, says that, in any system of closed currents, the current has, on the whole, no preponderance in any direction. As an illustration of the meaning of this, divide the whole space occupied by current into a very large number, say n, of equal small volumes, and draw n vectors from a fixed point, representing the current in each volume. If these were forces acting upon the point, they would exactly balance. This may be seen by first noting that a closed *line* has no preponderating direction, since it returns into itself, and next that we may split up any system of current into closed tubes of infinitely small section, each conveying a definite current, and that, although the section of a tube may vary, yet the density of current then varies exactly inversely; consequently v. $\Sigma C_1 = 0$ for any tube, as for a closed line, and hence v. $\Sigma C_1 = 0$ universally. Similarly v. $\Sigma B_1 = 0$, and the same for all the quantities with the suffix 1, since they have no convergence.

14. But we do not have v. $\Sigma B_2 = 0$, since the lines of B_2 are not closed. Let B_2 be electrostatic force, and consider a tube of force of section dS starting from one conducting surface and terminating upon another. $B_2 dS$ is constant, although B_2 and dS may vary along the tube, and this product is numerically equal to the amount of positive and negative electricities at the terminal sections of the tube upon the conducting surfaces. If we join the ends by a tube whose axis follows the shortest distance between them, and let the same amount of force as went from + to − electricity along the real tube return by the other, we have a closed tube, and v. $\Sigma B_2 = 0$. Consequently v. ΣB_2 for the real tube is numerically equal to the product of the amount of terminal electricities into the shortest distance, l, between them, and is directed from + to − along l.

As a magnetic illustration, let there be a cylindrical magnet of length l, and of any section, with plane faces perpendicular to l, uniformly magnetised parallel to l, and let B_2 be its magnetic force. Then v. ΣB_2 throughout all space is numerically equal to the whole magnetic moment, and is directed from the N to the S end, parallel to l. We may verify this as follows:—Given that the magnetic force in a cylindrical space similar to that of the magnet is of uniform strength B parallel to l, and directed from left to right say, and that outside the space there is no magnetic force at all, what is the distribution of current and of magnetism that would produce such a field of force? We must find the curl of B for the one, and its divergence for the other. Plainly the latter is B per unit area of the terminal faces, positive at the left end, negative at the right. Hence the left terminal face has surface density of magnetism + B, and the right − B. The curl of B is plainly confined to the curved surface of the cylinder, where B is tangential, and suddenly changes from B to zero in passing through the surface from within outward. Turn B at the surface through a right angle, and we obtain the surface curl. The current, therefore, circulates round the curved surface of the cylinder in planes perpendicular to its length, and is of density B per unit of length of the cylinder. The magnetic fields of this current, say B_1, and of the terminal magnetism, say B_2, together produce the uniform field of strength B within and zero outside. But for the former we have v. $\Sigma B_1 = 0$, and since v. ΣB is plainly = B × volume, and therefore = magnetic moment, and directed from left to right, the same must be true for v. ΣB_2, *i.e.*, for the magnetic force of the magnet with which we started. In fact, what we have done is to make a current flow round the magnet of such a strength and direction that the external field of force is exactly annulled, and of course we make the supposition that the magnetisation is rigid, or unaffected by its exposure to the magnetising force of the current. Now, on the understanding that the force of the magnet is derived from the magnetic potential as well within as without the magnet, we see from the above that the internal force of the magnet is annulled at the same time as the external by the superimposition of the magnetic force of the current, leaving only the uniform field B. On the other hand, if we were to employ the "electro-magnetic definition" of the internal force of a magnet, we should find that the current field exactly neutralised that of the magnet, both within and without.

15. Going back to Z, A, B, C, D, we have, in spite of the identity of the potential property of their constituents with suffixes 1 and 2, and of the energy properties as above mentioned, a striking apparent dissimilarity in the mode of derivation of any term from the preceding in the first set, as compared with the second. Thus, in the first set we have $A_1 = \text{curl } Z_1$, $B_1 = \text{curl } A_1$, and so on throughout, whilst in the second set we have the two operations of divergence when a scalar is derived from the preceding vector, and of space variation when a vector is derived from the preceding scalar. Now it is very remarkable that (as was discovered by Professor Tait) these three operations of curl, divergence, and space variation are really only three different forms of the same operation, the effect varying according to the nature of the function under examination.

We have hitherto used the symbol ∇P to express the resultant space variation of P per unit length, but have applied ∇ only to scalar quantities. Let a scalar function be given, as for example the temperature at every part of space, single valued at any point. Nothing is needed to specify it but its magnitude, it having no direction. Owing to this, its variation from point to point is one merely of magnitude. Measure its rates of increase $\frac{dP}{dx}$, $\frac{dP}{dy}$, $\frac{dP}{dz}$ in three rectangular directions, x, y, z, and call them X, Y, Z. In directions x, y, z draw vectors of lengths X, Y, Z, and compound them (as forces, velocities, displacements, &c.). The resultant vector, say R, shows the direction and rate of greatest increase of P, and, with Hamilton's symbol, $R = \nabla P$. The above method of forming R is what we are literally told to do when we use the full expression for ∇, and its effect upon a scalar is to give a vector expressing the most rapid space variation. There being, as before mentioned, merely a variation of magnitude concerned, there is little difficulty in conceiving the nature of the space variation of a scalar.

Now it appears that when ∇ is applied to a vector, it gives its curl and its convergence respectively. This extraordinary effect of ∇ is not easily to be understood, although symbolically it works out very simply, for there is undeniably a certain amount of mystery about the rules for vector multiplication. But we may gain some insight into the matter by examining in what manner a vector may vary, and by analysing simple cases.

16. In the first place we see that, given a definite vector, as electrostatic force, for every point of space, it may vary as we pass from one point to another as well in its direction as in its magnitude, and it is evidently not an easy matter to form an idea of what its resultant space variation may be if we endeavour to follow the rule for a scalar in the last section. In fact the construction fails, and obscurity prevails. But let us completely separate change of magnitude from change of direction, by starting with a vector which is everywhere directed the same way, and which can, therefore, suffer only change of magnitude. Let its direction be parallel to x, and its magnitude at any point be X. Regarding this as a scalar, it is clear that there is a certain direction in which X increases most rapidly, and that we can find it, and the rate of increase, by the construction for a scalar, viz., the resultant of vectors of lengths $\frac{dX}{dx}$, $\frac{dX}{dy}$, $\frac{dX}{dz}$ drawn in the directions of x, y, and z.

But this will give us neither the convergence of X nor its curl. To obtain them we must separate the space variation of X into two portions, first variation it its *own* direction, and next perpendicular thereto. We may easily recognise a manifest distinction between these two.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XXII.

Our space having been unexpectedly, though unavoidably, contracted, we are obliged for the present to omit giving, as originally intended, a complete illustration of the most convenient modes of working out the tests which have been explained. We have only space for two numbers, which will close the practical instructions for the guidance of those interested in the subject. Having gone through all the ordinary practice in the testing room preceding the shipment of a cable, we shall complete this series with some remarks on the duties that necessarily follow when the manufacture ceases.

Cable factories in London are always on the river side, for convenience of shipping, the cable ship being moored as near to the works as circumstances will allow. The cable is usually run out near the roof, passing overhead, and in some cases crossing the portion of river between ship and shore on guiding wheels raised on a platform fixed on barges. We are chiefly concerned with the details of the electrician's duty, and during shipment this is all, or nearly all, confined to the testing room. A day or two before the shipping commences a set of leads for communication with the ship is laid down in the river bed, the ends being carried respectively to the testing rooms on board and ashore; there are five or six of these leads lashed together, each being

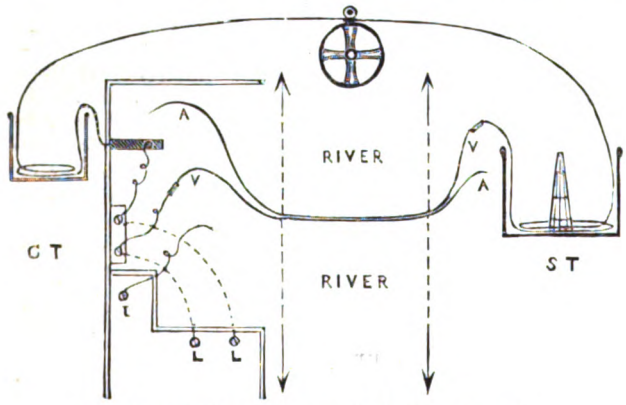

FIG. 46.—Testing arrangements during shipment.

sheathed for protection. Three of them will be generally quite sufficient for testing purposes, the rest for signalling from the ship's tanks to the cable tanks, &c. The former are numbered 1, 2, 3, and are called ship leads. As soon as they are properly laid and the ends conveniently disposed on board, they must be tested for copper resistance, capacity, and insulation, and the values recorded, to be accounted for in the ensuing cable tests, the C.R. to be deducted, and the number of divisions on testing for insulation also deducted from the deflections where necessary. When shipment is about to commence it is usual to alter the connections of the ends at the large commutator, as explained in an early number. This end is sometimes the point first sent over to the ship, as, for instance, when a length of cable is tapered being larger for the first part of its length and purposely tapered till the minimum or deep sea dimension is reached. If this has to be laid with the largest part first submerged (as probably being spliced on to a shore end, always the thickest portion of all cables), the small end would be shipped first, as this going to the bottom of the ship tank the heavier end would be at the top, but if not, then the heavier end would be sent over first. During shipment each section is kept under continuous observation on the electrometer, as previously explained during manufacture. As there are generally three tanks in a cable ship, there may be, though it does not always so happen, three sections running over at one time; in addition to the electrometer observations the sections are tested at intervals varying from two to six hours, or, in some cases, once only every twelve hours. In Fig. 46 we have endeavoured to represent the arrangement now under notice, but confine our illustration to the shipment of one section only, the same instructions applying, however, to three at once. It is difficult to give a clear view of the details which concern the electrician on duty within the limits at our disposal, they are therefore somewhat crammed together, and we have placed only two separate ship leads, but sufficient for our purpose. The cable in the cable tank C T has one end connected to the commutator bar, the other passes over head, being supported on its course by guiding wheels whose rims are grooved, and each of which has a small jockey wheel, which, being also grooved, forms with the other a guiding hollow way by which the cable is eased as it runs along and is kept in its place; one of these is shown in the figure. The cable is supposed to be coiling into the ship tank S T, the end having been left out, as presently to be noted; the two ship leads are marked A and V merely for distinction. The point I represents the terminal for connecting up to the insulation and capacity tests, and L and L′ are the bridge terminals as formerly shown on the bridge plan; the connections are arranged as for a copper resistance test.

When the ship tank is ready and all preparations made, a stout rope is spliced to the cable end which is to go over first, and this rope is then stretched across over the wheels which support it as it runs along to the ship, and a donkey engine on board pulls it over, and thus hauls the end of the cable after it. Several fathoms are hauled over and conveniently disposed before putting any into the tank; the end is brought into the ship's testing room, and is ready for joining up when required, then the coiling in the tank is started. Turning now to the testing. As one end of the cable is on board and it is desirable to take the C.R. test with a metallic circuit, one of the ship leads is joined to this end and the two leads connecting with the bridge terminals are joined, one to the other end of this ship lead by a binding screw, and the other to the cable bar by a plug, the circuit being thus completed.

For taking the insulation test we might if we chose have the cable end on board free in air, and test direct by connecting the lead from I to the bar; but this course is not a safe one, as a rule, for the confusion on board at shipping time is very great, and the end would probably be touched by some one. It is best, therefore, to leave the ship lead connected as just explained and insulate the end which is in the testing room, hanging the end over a peg or placing it safely out of the way; the lead from I will then be joined to the bar, or this lead may be connected by a binding screw to the ship lead, and the bar (with cable end) left insulated. This way of testing saves trouble also in another direction. It is necessary to send a battery man over to the ship to connect up the cables, and if one section only is to be tested the capacity and insulation tests will follow the C.R. test at once, and no communication with the shore is necessary, after the announcement that the ship lead is connected, until the end of the operation.

The tests are all straightforward and the same as usual; one or two points, however, may be noted. It is customary to arrange the plan of shipment beforehand, the details to be chiefly considered being the weights of the various sections of cable, the trim of the ship, the question which lengths shall be first laid, the general order of laying, &c. Many sections are spliced together in one long piece, sometimes amounting to as much as 500 knots. Consequently, as the pieces are successively joined on, the resistance increases, until the time comes when the C.R. amounts to more than can be measured on the bridge with the ratio of 100 to 1, then more than with 10 to 1, and afterwards equal arms must be used, that is, 100 to 100, or 1,000 to 1,000. The lengths are never so great as to necessitate the reversal of the ratio, though the thing is possible at sea, and in the case of a submerged cable when earth currents are strong. The splices are generally made when a length is nearly all coiled out of its shore tank, and the joints, of course, have to be tested. Some disturbance at times accompanies the coiling out and the running over of the cable; the tests are apt to be affected, and when three sections are being shipped at once the effect is stronger. Allowance must then be made

Digitized by Google

for this fact in the movement of the spot during insulation tests. For this reason some electricians only test running sections (as they are called) during breakfast and dinner hour, the cables generally, though not always, ceasing running at these times. We have mentioned that the running or shipping sections are kept continually under observation on the electrometer, and as each length when tested must be first disconnected from that instrument, the operator must be very careful to join it up again when he has finished. The insulation test being the last in turn, and requiring 200 cells at least, it is well to apply a short charge immediately at the close of the operation of an opposite kind to that with which it may have been taken, the object being to neutralise the remaining charge before restoring the connection with the electrometer. When three cables are running over at once each will be joined on board to a different ship lead. The connections should be always recorded in a book laid open for the guidance of those successively coming on duty; the resistances of the ship leads also and the lengths of each surviving section at the time must be entered, and every change noted, a fresh entry being made every time to avoid confusion. The cables are identified by the numbers of the shore tanks from which they are being coiled out. The entry is made somewhat in this form:—Tank 4, length = 70 knots, on 4 core and 2 ship lead, C.R. of ship lead = ·2. Tanks 3 and 7, length 98 knots, on 7 cable and 3 ship lead, and so on. The core and cable leads refer to the connections on the commutator, as explained in the early number. As before stated, the intervals between testing these running sections are various, but the electrician on duty should be informed of the progress of shipment in every case, and when a section is to be shipped in a certain length he must be sure to take a test shortly before the end goes over. The rate of running is from two to three knots an hour, so that where a length, for example, of 50 knots is to be shipped he should know when about 48 knots have gone, and at this time take his test; at any rate, it is advisable to get it finished as near as he can to the time when the cable must be disconnected from the testing room. The tankmaster will give him notice when the end should go over, but it is safer also to keep his own eyes open. The absolutely final tests are all taken after every section is on board and the cables are all under water in the tanks. A C.R. capacity, and insulation resistance test with both currents are taken, the cables being put to earth for two hours between each current. When the total length on board is great there may be, perhaps, eight or ten separate lengths; the best way to test these is to arrange with the battery man who connects up on board to join up all the lengths successively and in a known order for C.R., then for capacity and insulation resistance, communication being made with him by an electric bell that he may know when to connect and disconnect. When the last insulation test with one current is finished the man on board will commence joining up in same order over again for testing with the other current. The cables will each have been put to earth as they were tested, and each will have been to earth long enough when its turn comes for this other current, as the insulation test is one for 10 or 15 minutes.

There is a duty that sometimes falls to the assistant electrician at this time, though in some cases it is postponed till the ship is at sea and time is available for writing when nothing else can be done. This duty consists in making up a complete statement of the construction of the whole cable that will finally be submerged in one length. As previously explained the length is made up of coils of core successively joined on and afterwards sheathed. Each coil is numbered, the numbers running consecutively, but they are not all joined on in the regular order of their numbers. As they are added on their numbers are entered in a special book, and since there are several tanks for the different sections the total of the whole length is spread over the various pages of the book. It is necessary, therefore, at the time of submergence to have a list of the order of joining on from beginning to end of the whole cable. Between every two coils is a joint, these also being regularly numbered, and the list is made up by entering the whole of the coils and joints in the exact order in which they were worked into the cable. The test is ruled in columns, and contains the numbers of the coils, line after line, in black ink, and between each two the number of the joint which connected them together is in red ink. Other particulars are also entered in list, but this is the essence of it. It is very valuable as a record, since it is possible by its means to tell in what particular coil a fault afterwards appearing is located—that is to say, reference can be made to the details of the manufacture by this identification, as the time when the core was made, that also of the joint, and any other facts bearing on the question. The history of a joint as to the time when it was made is sometimes suggestive. Joints have been found to have failed, and, when traced, the cause has been seen to be the weather at the time of making. When made in exceptionally cold weather they are known to have been perfectly good at the time, but proved to have turned out weak from the great change in temperature at a later date.

LITERATURE.

The Electric Light—Electric Light Installations. By Dr. A. v. Urbanitzky. [Hartleben, Vienna and Leipzig.]

These two small works form Volumes III. and XI. of a useful series of publications upon electrical subjects edited by Hartleben, of Vienna and Leipzig, which, it seems, is intended to comprise all that has yet appeared, in the way of description and data for practical application, in the pages of all nations. As in most German works of this kind, there has been an immense amount of labour bestowed on collation and arrangement, and the reader may, without difficulty, turn to any of the various divisions of the subjects; as, for instance, the power necessary for the work to be executed and the cost. There are details of many existing installations, some no further away than the Savoy Theatre and the London Docks. We strongly recommend to the notice of local authorities and others who have to deal with "high pressure" or "alternating" promoters the pages devoted to the dangers attending the employment of electricity. The death on board the "Livadia" from an alternating current and others are described. At Pittsburg, Pa., a workman touched a railing put up round a machine, which by some means was in connection with the leads. He was observed to grin and gesticulate, fell backwards, and died immediately. A dark yellow stain running round the throat, and a long furrow extending from the thigh to the ankle of the right leg, showed the path of the current. Otherwise his appearance was that of a man who had fallen into a deep sleep.

There is little attempt made in these books to do more than describe accurately the subjects dealt with, and it seems a pity that the relations of the practical units to the C.-G.-S. units, which do not concern those to whom mainly the books are useful, should be given at all, and worse still that there should be an error in the statement of them. Thus the farad or unit of capacity in the electro-magnetic series is given as 10^9 times the C.-G.-S. unit, instead of 10^{-9} times that unit, which is its proper value. Again, we read "1 h.-p. $= \frac{\text{amp} \times \text{volt}}{746}$," which means literally nothing at all that is true. What the author means to say is that the reading of a certain power in horse-power units is $\frac{1}{746}$ of the reading of the same power in volt-amperes, or 1 h.-p. = 746 volt-amperes. There is a similar want of exactitude in describing a *cheval de vapeur*.

The first volume is entirely devoted to lamps in general, but the two volumes, which are both from the pen of D. A. v. Urbanitzky, must be taken together as one work. They are very thoroughly illustrated.

CORRESPONDENCE.

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Commenting on Ball's so-called unipolar machine in your impression of April 14, Dr. Paget Higgs makes some interesting remarks upon the action of the Gramme ring. He describes some experiments with the object of disproving "the false notion that the inside wires were of *nil* effect in producing electromotive force," and contends that "the inner wire is as efficacious as the outer wire." Whilst reading with respect anything Dr. Higgs says about dynamo machines, I cannot see that it is proved that the inner wire of the Gramme ring has the efficacy he claims for it. He remarks that the true function of the ring is that of "a particular form of electro-magnet." That it is this, and something more, has, I think, been generally admitted, but what is the particular form ascribed to it? The experiments related show the necessity for an unbroken ring, but do they afford a proof of the equal efficacy of the inner wire? I venture to think not. No practical E.M.F. is developed, Dr. Higgs says, when the iron is in detached pieces, in the ring, "although the 'magnetic screen' is still there." Would it not be more correct to suppose that under these circumstances the magnetic screen is not there? It was shown by Antoine Breguet, as clearly explained by Professor Silvanus Thompson, in "Electric Illumination," that with a continuous iron ring the lines of force are to a great extent screened from the inside wires, and this fact is quite capable of ocular proof. It is so screened because the lines of force entering the ring from one pole pass invisibly through the iron, and out again near the other pole. But with a ring consisting of magnetically isolated pieces of iron the lines of force which enter are very much smaller in number, and they must pass out again somewhere, as iron conducts but does not obliterate or subdue them. In so passing out some will be cut by the inner wires in a sense which tends to neutralise the E.M.F. developed in the outer wires. Thus, if a small piece of iron be placed near one pole of a magnet, it can be seen by means of a card and iron filings that lines of force enter it from the magnet and leave it from the side remote from the magnet. But if one end of a bar or rod of iron be put in its place, and especially if the other end be brought near the other pole, the lines of force will be seen to enter the iron, but not to leave it, till they pass out at or near the distant end. So in the Gramme ring.

Dr. Higgs argues that the incompletion of the ring does not affect the "magnetic screen," and by inference that Breguet's screen theory is wrong. I have tried to show that an incomplete ring means an incomplete screen, and that its completion is as necessary to the ordinarily accepted theory as to that which Dr. Higgs advances, but of which he does not give any particulars, beyond stating that it involves an "electro-magnet system."

I think it may also be argued from the following experiments that the inner wire of the Gramme ring cannot be as useful as the outer wire. If (*a*) a pole of a bar magnet be plunged into a circular coil of wire, an E.M.F. will be equally developed round the coil, because the lines of force are cut equally on all sides. If (*b*) simultaneously with passing the pole into the coil an opposite magnetic pole be passed in the same direction along one side of the coil, then I suppose the E.M.F. developed in the portion of the coil between the two poles will be greater than in the portion remote from the outer pole, because in the latter region the magnetic field is weakest—the increase in the lines of force is least. Again (*c*), if experiment *b* be repeated, but with a soft iron bar substituted for the bar magnet plunged into the coil, an E.M.F. will be devoloped due to the lines of force between the outer and inner poles, but as the inner pole is created by the induction of the outer one, the lines pass principally directly between the two, as may be seen by scattering iron filings over a card, and in this region, therefore, the E.M.F. will be principally developed. It seems to me that this last experiment must illustrate to a large extent the action of the Gramme ring. The filings show that very few lines of force enter the iron at the side away from the pole; in fact, they give Breguet's illustration exactly. (*d*) Repeat experiment *c*, but with two similar poles, one at each side of the iron bar, and the lines of force are seen to pass into the iron at both sides, and to thereby illustrate the superiority of the flat Brush ring with its double poles over that of Gramme.—Yours, &c.,

W. M. MORDEY.

CARBONS IN ARC LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I ask for information through your columns on the following questions?

Supposing the carbons of an arc lamp to be surrounded by water, light would be impossible, but what would be its equivalent?

Might it not be that with the decomposition of the water, and the combination of the oxygen with the carbon, the result would be an increase of the passing current, or, possibly, a reverse one?

Or, in another form:—Suppose a vessel to contain coal dust and water, and the water to be decomposed by an electric current, what would be the result?

As to obtain heat we first have to light a fire, so by starting the combustion of carbon by electricity may it not be that electricity would follow on?

If a battery on this principle were to be successfully constructed, dynamos would be unnecessary, and powerful generators of little weight and capacity would render the application of electricity to vehicles and locomotives possible and easy.

Surely this is worth experiment.

In the hope that some of your readers may think it so, I ask you to insert this letter in your journal.—Yours, &c.,

H. B. R.

26, Upper Hamilton-terrace, N.W., April 30, 1883.

BOOKS ON ELECTRICAL SUBJECTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you kindly allow me to say a few words anent good and bad books on electrical subjects? I am one of the public engaged in the erection of electric lighting apparatus, and I venture to offer a note or two of my experience of the usefulness of books to a practical man. I have read the works of Professors Tyndall, Maxwell, Jenkin, Rankine, and the lectures of many others on electrical and cognate subjects, with one aim in view, namely, the acquisition of knowledge pertaining to my trade. With the exception of Rankine on engineering I cannot say that I have been benefited in the least by careful study of those works. They do not tell me what to do. They do not give any idea of the machines, lamps, or conveying systems used by electrical engineers, and appear to me to be, in a word, only useful to students of theoretical electricity. In your notice of Urquhart's "Electric Light" you appear to have recommended the theoretical books, and to condemn such works as give descriptions of the things actually used and the way to handle them. I think such books as "Electric Light" are by far the most generally useful, especially to practical men like myself, and I have derived more useful information from it than from all the other electrical works I possess.—Yours, &c.,

AN ELECTRICAL ENGINEER.

RESISTANCE OF CARBON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can any of your readers refer me to any papers on the following subjects:—1. The numerical values of the variation of the resistance of carbon and silicon at different temperatures. 2. The resistance of boron. 3. Does the

Digitized by Google

change of form said to occur in carbon incandeseence filaments after prolonged use take place in any other conductor?—Yours, &c., TYRO.

May 2, 1883.

STRENGTH OF STEEL MAGNETS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any of your readers oblige me with Häcker's formulæ regarding weight and strength of field magnets?—Yours, &c., ENQUIRER.

COMMISSIONERS OF SEWERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My attention has been called to a paragraph in *The Electrician* of last week, in which my name is mentioned in connection with the proposed lighting of the City by electricity. In justice, not to myself, but to the Commissioners of Sewers, I have to ask the favour of your allowing me to say a few words in answer.

The commission requested me to report on the various tenders presented to them entirely on account of what they had acquired and learnt concerning me. I had not a single friend amongst them, the gentleman who proposed me was a stranger until a few weeks before the election came off. Who my seconder was I even now do not know. With the exception of one other gentleman with whom I have been officially brought into contact over the matter, I have not the privilege of being acquainted even by sight with any member of the commission.

I was not the only one the commission appointed to report on the subject, neither does my name stand first.

With regard to myself I cannot in good taste speak; that I can leave to those who have long professionally known me, should they deem there is any necessity on their part to do so. But, perhaps I may remark that you, sir, have not unfrequently for some time past done me the honour of mentioning my name in your paper, and that in a very different manner indeed from the way you wrote in your last issue.

If the report which I have presented to the Commissioners of Sewers had been made public, it would, of course, have been right and proper for you to criticise it in as stringent a manner as you pleased. But when two independent reports are before the commission, one from him whom you mention as declining to act as *collaborateur* with me, and the other from myself, and the commission are about to decide which shall be adopted, his or mine, I cannot but think that you will, on reflection, agree with me, that in common fairness such a paragraph, prejudging mine, should not have been inserted in your paper.

Whether such a personal attack as your article, read as a whole, appears to be is not one calculated to prejudice the minds of the commissioners, and cause them to lean in favour of adopting the report of him whom you describe as "standing in the front rank of those connected with electrical matters," I must leave you to judge.

I should, however, have thought that any report emanating from this great authority on electric lighting could well have been left to take care of itself—if opposed to mine—without any aid from your journal.

May I ask whether "rumour," sir, who appears to have acquainted you with so much, has mentioned the name of my so-called *collaborateur*, and also whether we were opposed on another matter some time ago, which necessitated my adopting a very decided course of action?—Yours, &c.,

MUSGRAVE HEAPHY.

19, Lombard-street, E.C., 30th April, 1883.

[We were altogether unaware that any report had been sent in by Mr. Heaphy or any other authority till we received the above letter. Rumour has not given us the information hinted at by our correspondent in his last paragraph. We have no reason to withdraw our previous remarks, thinking that the ablest available talent should be at the service of the Commissioners of Sewers, and surely we may be allowed to suggest that this talent lies among men who have devoted their lives to electrical and cognate subjects, and have made their mark in the history of science. Mr. Heaphy must be congratulated that so high an opinion is held of his abilities after comparatively a short career in electrical work. Mr. Heaphy informs us that it is more than six years since he first commenced investigations into electric light matters.—ED. *E.*]

HIGH SPEED DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Are not high-speed dynamos a mistake? I notice that the large dynamo machines of Edison and Gordon are coupled direct to the engine which drives them, whereas in very high-speed dynamos, as in that of Ferranti, the efficiency of which we have heard so much, the shafting and belting are very considerable items in the erection of the installation. I think the Ferranti installation at the Westminster Aquarium is a fine exhibition of shafts, belts, and pulleys, and although the machine may be the most interesting, it strikes me that high efficiency cannot be obtained when hundredweights—perhaps tons—of machinery have to be actuated at high speed before the necessary power is communicated to the dynamo. Besides the friction of this, the air churning has to be taken into account, and 6,000ft. per minute in belting, some 20in. wide altogether, is not particularly suggestive of a dead calm. Lastly, the engineer notices the great strength of the building, which is most requisite when power in such quantity has to be geared.

I should very much like to hear other opinions about this, but it seems to me that when the necessary foundations, pulleys, shafts, and, worst of all, belts are placed in position to propel such a machine as the one mentioned, most of its cheapness and efficiency and all claim to compactness is gone.—Yours, &c., W. S. H.

TESTS OF INCANDESCENT LAMPS.

[We have been favoured by Mr. H. Joel with the following table of tests. It must be noticed, however, that such tests are of limited value, inasmuch as the various lamps are not maintained at the normal candle-power for which they are constructed. Our own experiments show that the Maxim lamp, for example, is far more economical and efficient at 50 or 60 candle-power than at 20 candle-power.—ED. *E.*]

COMPARATIVE TESTS OF DIFFERENT INCANDESCENT LAMPS AT 20 CANDLE-POWER.

Name.	Resistance cold ohms	Current in amperes	E.M.F. in volts.	Watts.	Remarks.
Maxim	66	1·56	56	87·36	Average of 7 lamps.
Maxim	110	1·1	65	71·5	Average of 5 lamps.
Swan	150	1·38	93	128·34	Average of 2 lamps.
Swan	67	1·5	51	76·5	One lamp.
Swan	63	1·46	47	68·15	One lamp.
Woodhouse and Rawson	69	1·53	57·5	90 85	Average of 10 lamps.
Duplex	130	1·32	94·4	124·708	Average of 10 lamps each tested in series
Edison	245	0·82	112	91·84	Average of 10 lamps.
Gatehouse.....	120	1·0	64	64·0	Average of 10 lamps.
Gatehouse.....	100	1·25	54	67·5	Average of 10 lamps.
Gatehouse.....	150	0·9	72	64·8	Average of 10 lamps.

All the above tests were made with the same instruments, and under the same conditions, 20 candle-power being observed throughout.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 27th April amounted to £2,990.

AMALGAMATION FOR THE SUPPLY OF ELECTRICITY.

We have not yet heard the result of the meeting convened in New York, on the 20th ult., for the purpose of considering the desirability of combination among the electrical companies of that and other cities; but whatever may have been decided on that occasion, sooner or later the propositions then set down for discussion will have to be definitely adopted, not only in the United States, but in most of the countries of Europe. The necessity for united action on the part of the various undertakers engaged in supplying electricity is every day becoming more obvious; and although the urgency for it is perhaps not so pressing in this country as in some other places, prudential considerations should induce us to shape our plans in good time on the basis recommended by the "Committee on Underground (Electrical) Communication" in New York, rather than proceed in a reckless course of competition, only to retrace our steps when the mischief is done.

There are no exact statistics available in reference to the purveyors of electricity in this metropolis. In some respects we are better off, in others probably worse, than our friends across the Atlantic; but, on the whole, the arguments applicable to them will apply to us. According to a circular convening the meeting above referred to, there are in New York twenty-one corporate bodies engaged in transmitting electric currents for the use of the public. Of these, eleven are telegraph companies, including fire alarm and police telegraphs; one is a telephone company; five are electric lighting and power companies, and four others are for miscellaneous purposes—all these companies carrying their wires overhead, or "exposed to view" as the circular puts it, along the routes of a greater part of their entire systems.

It is not quite clear whether this includes every one of the New York electrical companies who possess wires, or only those who erect them above ground. The point is immaterial, however, for the indefinite multiplication of overhead wires is as objectionable on grounds of public safety as the indiscriminate cutting up of the streets would be on grounds of economy. It seems to be assumed, and we think quite correctly, that overhead wires must come under; and that in any case the additional wires required for electric lighting will have to be placed below ground. The question then arises, Is each independent company to apply for powers to take up the roadways and to construct separate subways for every separate system, or are they all to combine, either in a common purse, or in the construction, so far as may be practicable, of a common subway? Several of the existing companies possess what are called "underground rights," that is to say the powers legally required to break up the streets, and some of them have already made use of these powers—notably the Edison Company, which has now in successful operation about sixteen miles of underground wire for supplying electric light.

Now, it is obvious, as the circular pointedly remarks, that the other twenty companies cannot follow the Edison Company's example. Even if they were persuaded or compelled to do so, the expenditure of capital and the disturbance of the streets would become an intolerable burthen. How, then, are the various interests to be so far combined as to form a working scheme, so that the wires of all the companies may find a safe and comparatively inexpensive lodgement underground? The subway scheme is, of course, very simple, and the ideal at which the promoters aim is that wherever an alarum, a telephone, a time wire, a stock register, lifting or pumping power, or an electric light, is required, an attachment to the main supply systems should be practicable at once and without molesting the street.

A system so comprehensive and perfect as this may be considered perhaps a little too ideal, but so far as its mechanical difficulties are concerned it is a quite practicable one. The real difficulty is electrical. To make such an enterprise profitable it must have for its customers the telegraph signalling companies of all classes as well as the electric lighting companies. To carry these two sets of wires side by side has hitherto been an electrical difficulty, but it is one which the committee confidently believes they are able to solve by means of patents already taken out relating to insulation, induction, and various other matters that have to be dealt with in a problem of this kind.

The committee, in fact, have issued two circulars, one

Digitized by Google

inviting attendance at a meeting of all the companies interested; the other giving a list of patents acquired by the Gramme Electrical Company—the prime mover in the matter under consideration. The first circular is the cannon; the second the shot with which it is charged, a four hundred pounder it may be called, for the number of patents claimed by this company and its auxiliaries actually reach that figure; and the object of the discharge is intended, we presume, to strike terror into any smaller detachment presuming to fire an independent scheme of its own. Its effect, of course, will depend more upon the quality of the shot than upon its weight. But the moral is the same for us who are at present mere lookers on—namely, that the conviction has already come home to a large and influential combination of electrical companies that their future prospects will greatly depend upon judicious co-operation with telegraph and telephone companies for the establishment of a system of electrical underground communication common to them all.

THE COST OF ELECTRICITY.

We give in another column a carefully drawn up estimate for a large electric light installation, together with the appendix attached to the estimate, giving the approximate cost of electricity as compared with gas. We have probably had greater advantages than most people in the study of this estimate, having been some time since favoured with a copy, and having discussed it more than once with those interested in the work. It is almost needless to say that the result is a surprise even to us, somewhat sanguine as we are of the merits of electricity when compared with gas, but although we have again and again gone carefully through the figures we have been unable to modify them to any considerable extent, not sufficiently, indeed, to interfere with the result, that under the circumstances specified electricity is far cheaper than gas. The Telegraph Construction and Maintenance Company is a company known, not only for its able mangement, but for its great, its extraordinary care to be always on the right side. In its work every possible contingency seems to be thought of and provided for, hence its long record of successes, and we cannot but feel that in entering upon a new branch of the applications of electricity as great or greater care will be expended in obtaining complete data and being over careful rather than otherwise in the estimating. There are many points which might be noted in this specification, but we must be content for the present to note but few of them. The Nottingham Corporation would be quite safe to accept the tender; there can be no doubt on that point. The risk, if any, lies with those who tender. Although the number of lamps mentioned is 60,000, this means that at least 120,000 lamps might be wired, for it is hardly conceivable that at any time more than one half the lamps in a town would be used at one and the same time. It has been suggested that attention might be called to the paragraph relating to "mains," and comparisons made as to the section proposed to be supplied and the sections required by the formula of Sir W. Thomson given at the York Meeting of the British Association (*vide Electrician*, Vol. VII., p. 295). It will be seen that the company propose to work for thirty days, to allow of a fair test of the apparatus, and a large proportion of the sum payable is held by the corporation till after this complete test. We shall be glad to receive the opinions of readers upon this subject, and hope so definite a scheme may lead to a great success.

THE PRACTICAL MEASUREMENT OF ELECTRIC CURRENTS AND ELECTROMOTIVE FORCE.*

BY PROFESSOR JAMES BLYTH, M.A., F.R.S.E.

Till very recently the measurement of the two electrical quantities—current intensity and electromotive force, was only, or, at least, mainly, needed for purposes of physical research, and hence the instruments employed were of the delicate and unportable kind usually found in physical laboratories. Provided perfect accuracy were secured, no special care was taken to make the instruments unwieldy or easily moved from place to place without detriment. Within the last few years, however, matters in this respect have considerably changed. During that time electricity, or, rather, electrical energy, has become a really marketable commodity, and already several companies have been formed for its supply, while the users of it both for electric lighting and electrical transmission of power are daily on the increase. This has created a demand both on the part of suppliers and users for handy, and at the same time, accurate instruments, whereby the amount of this energy can be determined.

In order to measure the energy in any part of a given electrical circuit two quantities require to be known. These are the electromotive force acting in that part of the circuit and the quantity of electricity passing through it. The former is expressed in volts and the latter in colombs, the volt and the colomb being the adopted practical units of electromotive force and quantity of electricity respectively.

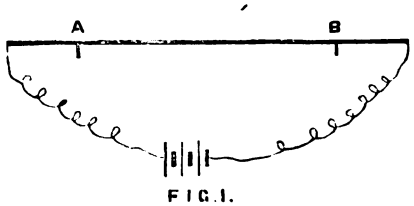

FIG. 1.

Let A and B be two points in any electrical circuit which a current C is passing, and let E be the difference of potential, that is the electromotive force, between A and B; then W, the electrical work spent in driving a quantity, Q, of electricity from A to B in the time t is

$$W = \frac{t}{EQ} = E\,C\,t.$$

Hence rate of doing work $= \frac{W}{t} = E\,C$. By dividing by 746 this is reduced to horse-power. Hence

$$H.\text{-}P. = \frac{E\,C}{746}.$$

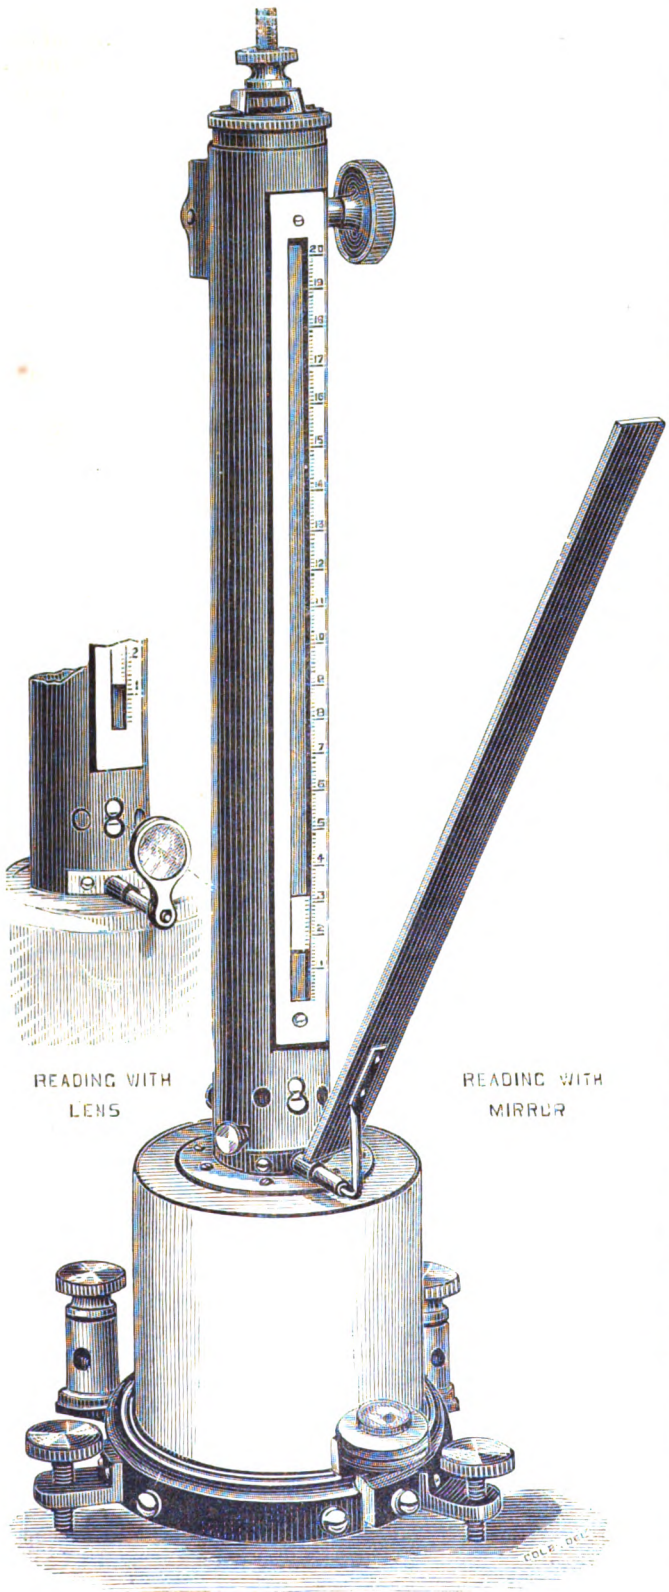
From this we see at once that, unless we employ some form of meter which measures energy directly, we must have two instruments before we can measure the electrical energy in the part A B of our circuit, the one a galvanometer or current meter for measuring C, and the other a voltameter for measuring E.

For laboratory work merely, any of the well known forms of galvanometer, such as the tangent galvanometer, the sine galvanometer, or various forms of electro-dynamometer, are very accurate and suitable. As already said, however, they are all too delicate and bulky to satisfy the requirements of present electrical engineers. Hence various inventors have endeavoured to produce modifications of the instruments which shall have the properties of small size, accuracy, and portability. Excellent examples of such are the ammeter of Professors Ayrton and Perry and the graded galvanometer recently invented by Sir William Thomson. In all instruments of this class

* Abstract of paper read before the Society of Arts, Glasgow.

Digitized by Google

the current strength is deduced from the deflection produced by it on a magnetic system suspended so as to be free to move in a magnetic field of a nearly as possible constant intensity. This field may be either that due to the earth's magnetism or be produced artificially by suitably-placed



permanent magnets. To get the current strength, some function of the angle of deflection (usually the tangent) is multiplied by a certain constant peculiar to the instrument. This constant involves as a factor some component of the intensity of the magnetic field, and hence will vary if that intensity varies. Now, as is well known, this intensity varies both on account of variations in the earth's magnetism, and still more from the presence of large masses of iron or dynamos at work in the neighbourhood of the instrument. Hence, unless special precautions are taken, the readings of of all such instruments are apt to be in error. Besides this the magnetism of the permanent magnets which produce the magnetic field is subject to gradual variation in the course of time, arising from the fact that no substance possesses perfect magnetic rigidity; and hence, on this account, the instruments referred to require to be periodically readjusted. To do away with the need for this readjustment as far as possible, and to be able, unless for very strong currents, to read the current in amperes at once, I have recently devised the instrument represented in Fig. 2, and which may be called a solenoid galvanometer.

It consists of a hollow bobbin, round which a length of insulated copper or German silver wire is wound, constituting the solenoid. The bobbin is placed with its axis vertical, and a hollow cylinder of thin soft iron is placed so as to be free to move vertically with its axis, connecting with that of the solenoid. This iron cylinder or core is suspended from the lower end of a spiral spring, the upper end of which is attached to the top of a tube movable up and down by a rack motion in a fixed exterior tube, which it accurately fits. When no current passes through the solenoid, the weight of the iron cylinder is so adjusted relatively to the extension of the spring that it hangs with a certain part of its length (about a third) out of the hollow of the solenoid. This position is determined accurately by two fine black lines on a white surface, drawn round the iron cylinder, about one centimetre from its upper end. These lines are viewed by means of a line through a vertical slit in the exterior brass tube, across which a fine wire is stretched. When the fine wire is seen exactly between the two black lines, the cylinder is in its zero position. When in this position the lower end of the tube, to the top of which the spiral spring is attached, has the zero point of the vernier, which it carries, opposite the zero point of a vertical millimetre scale. To adjust these two zero points (which requires to be done only once for all) a fine screw is provided whereby the top attachment of the spiral spring can be raised or lowered a little as required.

When the current to be measured passes through the solenoid the soft iron cylinder is sucked in by the electromagnetic attraction. It is then raised against this attraction by the extension of the spiral spring till the black lines are seen in their zero position. The number of millimetres through which the spiral spring has been extended shows by reference to a table the current strength in amperes. For greater convenience another scale placed opposite the millimetre scale shows at once the current in whole amperes, the fractions of an ampere, when required, being got from the table and millimetre scale.

The graduation of the instrument requires to be done with particular care, but it is obvious that when once one has been done to serve as a standard all others can be very easily and speedily graduated from it.

The graduation may be effected by the tangent galvanometer, the electrolysis of water, or any of the ordinary methods for determining the strengths of an electric current. I have employed both the former methods, in order that the one might serve as a check upon the other, but have relied chiefly, especially for strong currents, upon the method by the electrolysis of water. In graduating by this method the instrument is placed in circuit with a Grove battery, and a suitably constructed water voltameter. In the same circuit is included a rheostat arrangement, where, by varying the resistance in the circuit, currents varying very little from each other in strength can be readily obtained. Having adjusted the current to suit any particular division of the millimetre scale, the mixed gases from the voltameter are collected by displacement in a glass vessel of known capacity, usually 50cc. or 250cc. or 1,000cc. The time taken to fill this vessel is accurately observed by a stop watch, and, at the same time, the temperature and height of the barometer noted. From these data the current strength

Digitized by Google

corresponding to that particular division of the millimetre scale is calculated from the formula

$$C = \frac{V \times 273 \times P}{\cdot 1764 \times t \times (273 + \theta) \times 760},$$

where

C = current in amperes.

P = atmospheric pressure in mm. of mercury.

t = time in seconds.

θ = temperature in degrees centigrade.

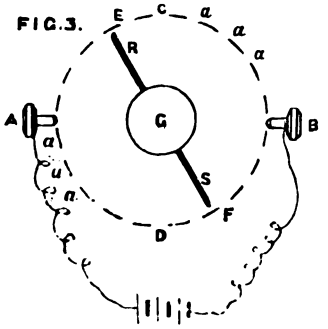
During the entire process of graduation a separate adjustable resistance is provided whereby the current strength is kept constant during the time of making an observation, although that time was never so long as to allow of any great variation in the current strength. In this way the instrument has been graduated from 0 up to 24 amperes.

From measuring stronger currents three arrangements may be adopted. These are:—(1) The use of a stronger spiral spring retaining the same solenoid and core. (2) Retaining the same spring and core, but sending the current to be measured through one only or any combination of the coils of the solenoid. (3) Shunting a known fraction of the current past the instrument.

To the first of these methods there are several obvious practical objections, and hence it has not been employed in any of the instruments as yet constructed.

For employing the second method a set of separate terminals is provided whereby the current can be sent only through the first, second, third, &c., or any combination of the solenoid coils. These terminals are numbered, and a reference to a table shows at once, in the column appropriate to each number, the current corresponding to any number of millimetres.

FIG. 3.



For employing the third method a set of separate resistance coils is provided, each having exactly the same resistance as that of the measuring solenoid. To secure this each is made of exactly the same length of the same wire as that surrounding the solenoid. When one coil is employed as a shunt the current indicated by the instrument has simply to be multiplied by two, when two are employed in multiple arc by three and so on. This form of shunt arrangement, although very accurate, has the disadvantage of rendering the instrument less compact and more unportable than is frequently desirable. To avoid this as far as possible I have adopted a second form of shunt arrangement which depends upon the principle of Wheatstone's bridge, and which will be readily understood from Fig. 3.

A C B D is a massive ring of brass or copper surrounding the sole-plate of the instrument, A and B being the terminals at opposite ends of a diameter by which the current enters and leaves the ring. At equal distances round the ring twenty gaps, a, are made, each of which is bridged by a wire having a known resistance which may be represented by a. G represents a horizontal section of the solenoid coil, which is supported on a vertical pivot passing through the sole plate. To the lower end of this pivot a horizontal arm is attached whereby the solenoid can be rotated through a right angle. Two projecting arms of brass, R and S, are rigidly attached to the opposite sides of the case of the solenoid. These are insulated from the case, but are in metallic connection with the ends of the solenoid wire. When the solenoid rotates, the outer ends E and F of the arms R and S make tight slipping contact with the metal ring A C B D. If a current, X, enter at A and leave by B, and if E and F be placed so that the line through E G F coincide with the diameter C D of the ring, it is obvious that no current passes through the solenoid. Let it be placed as shown in Fig. 3, so that there are seven gaps in the arcs B E and A F, and three in the arcs at E and B F, and let g be the resistance of the solenoid. By an easy application of Kirchoff's laws it can be shown that, if X be the main current, and C that in the solenoid G,

$$\frac{X}{C} = \frac{7a + 3a + 2g}{7a - 3a} = \frac{10a + 2g}{4a}.$$

Hence

$$X = \frac{10a + 2g}{4a} \times C.$$

The value of C is given at once from the millimetre scale, and X is formed by multiplying by the factor $\frac{10 + 2g}{4a}$. It is obvious that for all positions of the arm E F the numerator of this fraction is the same, and that for any position the denominator is the difference between the resistance in the arcs B E and E A respectively. Hence the reduction factor can in all cases be easily obtained.

The solenoid voltmeter—an instrument for determining the difference of potential between any two points of an electric circuit—is constructed exactly on the same principle as the solenoid galvanometer. The only essential difference between them is that in the voltmeter the solenoid bobbin is surrounded by a great number of turns of fine insulated copper or German silver wire, so as to have a great resistance, not less than 5,000 or 6,000 ohms.

The object of making the resistance so great is that, when the instrument is joined up as a shunt to the main circuit between the two points whose difference of potential is to be measured, it may not sensibly diminish that difference. The voltmeter is graduated in the same way as the galvanometer, and shows by reference to a table the difference of potential corresponding to the various divisions of the millimetre scale.

ELECTRO PULVERISER AND AMALGAMATOR.

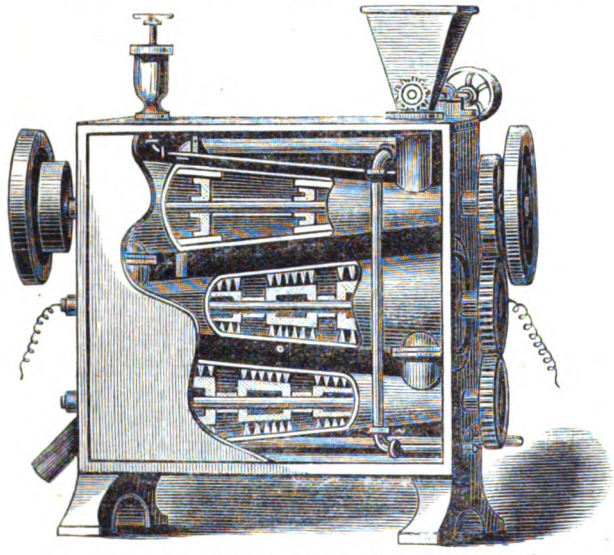
The Manes electro pulveriser and amalgamating machine, shown in the cut, is designed for saving the rusty and fine gold, also the quicksilver, that has been lost in hydraulic washing for gold on the coast of California ever since the commencement of hydraulic washing in the summer of 1852. It is said that the loss has been at the rate of from 20 to 35 per cent. of the precious metals and mercury, which, if saved, would amount to hundreds of millions of dollars.

Notwithstanding all the modern improvements in mining machinery, immense quantities of the precious metals are constantly washed away and irrecoverably lost. The value of this lost portion, according to various estimates, is very nearly if not quite as great as that of the metal secured. A great deal of engineering skill and inventive genius have been engaged in trying to devise means of preventing this great loss. This has generally resulted in placing various devices in the sluices to catch and retain the stray particles of gold or sulphuret. Some of these inventions have been more or less successful, but none of them have saved anything like a reasonable proportion of the valuable part of the metals.

The electro amalgamator, it is claimed, will save from 50 to 75 per cent. of all the gold and quicksilver that passes through the machine, as the rusty gold will be perfectly scoured and electroplated with quicksilver, and thoroughly amalgamated by the rapid action of the electrical steel brushes and steel mullers that revolve inside of the series of steel cylinders in the machine, placed one above the other, and made cone shape, and connected with spouts; the large end of one cylinder is placed under the bottom of the small end

Digitized by Google

of the next one, and so on, forming inclined planes for the sand or crushed ore to run down by its own gravity, which is assisted by streams of water and quicksilver, constantly fed into the machine from a hopper on the upper part of the machine; and the powerful current of electricity is constantly passing through the sands or ore, as it passes from one cylinder to another, and as it is thoroughly mixed at the same time with the quicksilver by the steel brushes, no gold escapes without having been thoroughly amalgamated. The material passes through a movable iron spout into settling tanks, where the cleaning up is done. The machine does not stop except when repairs are needed; the waste water of the sluice boxes is used for driving the machines, and but one



Manes' Electro Pulveriser and Amalgamator.

man is required to attend to each machine. The fine sands will be conveyed into the machines through screens of the proper size. This apparatus can be used in stamp mills for amalgamating purposes, and will surpass the old process of treating gold and silver ores. The inventor, Mr. James Manes, is now engaged at the new chemical works in Morrison, Jefferson County, Colo., for the Colorado Paint and Chemical Company, as chemist and metallurgist. Mr. Manes, as an inventor of mining machinery, is well known in this and other countries. The first one of the electro amalgamating machines has just been completed at the extensive shops of the Colorado Iron Works, Denver, Colo., and the models and complete drawings are exhibited at the office, 5, Windsor-block, Denver, Colo.—*Scientific American.*

ELECTRIC LIGHTING OF NOTTINGHAM.

Specification and Tender No. 1.—60,000 Lamps.

General Nature of the Installation.

The installation to consist of the necessary mains, machinery, reserve machinery and buildings, as specified below, for the continuous supply of a current of electricity to all the houses, warehouses, shops, factories, street lamps, &c., in the district marked on the map sent herewith, sufficient for the maintenance of 60,000 (sixty thousand) Swan lamps of 20 candle-power* each during 16 hours out of the 24, and of one-third of that number during the remaining eight hours.

Electromotive Force.

The current to be supplied at an E.M.F. of not more than 70 volts, and so that the Swan lamps can all be arranged "in quantity."

The Dynamos.

Five Gordon dynamos to be provided, four to work, one spare, each being capable of continuously maintaining 15,000 Swan lamps of 20 candle-power each for sixteen hours out of the twenty-four, when running at a speed not exceeding 150 revolutions per minute.†

The magnets to revolve, and the current to be taken off directly from the fixed armature coils without rubbing contacts.

The dynamos to be connected direct to the engines without belts.*

The Exciters.

Six sets of direct current machines to be provided to excite the magnets of the large dynamos, one set to be used for each dynamo, and one to be in reserve, so that it can be instantly connected to any one of the dynamos in case of its own exciter getting out of order.

The Engines (for the Large Dynamos).

Each dynamo will require when working all its lamps about 1,530 I.H.-P.

Two engines to be provided for each dynamo, to be coupled one to each end of the shaft. Each engine to be capable of developing 850 I.H.-P. Thus, ten engines in all are to be provided for driving the large dynamos. The engines to be compound, condensing, tandem, of the vertical inverted cylinder type. They are each to have one high pressure cylinder on the top of one low pressure cylinder, one piston rod carrying both pistons. They are specially designed for electric light work, with extra large crank shafts and bearing surfaces, and special methods for lubricating all parts without stopping. They are to be fitted with the best governors that can be obtained, and are to be in all respects capable of running at 150 revolutions per minute for sixteen consecutive hours in each day without ever stopping. They are to work at a pressure of 100lb. per square inch.†

The Small Engines (for the Exciters).

Six small engines to be provided for driving the exciters, each to indicate up to 60 H.-P.‡

These engines to be also compound, but will not have separate condensers; they are to be connected to the condensers of the larger engines.§

Boilers.

Thirty-eight flue-boilers, fitted with Galloway tubes, to be provided, capable each of developing about 220 I.H.-P., so that thirty of them may be at work and eight idle. Patent automatic steam-stoking apparatus to be provided, as also all the usual gauges, &c.

Steam Pipes and Connections.

All necessary steam pipes and connections to be provided.

Provision to be made for shutting off any boiler or any engine as required, and for removing any pipe without stopping the supply of electricity.

The Engine House, Boiler House, Coal Store, and Chimney.||

The general arrangements to be as shown in the tracing sent herewith.

Adjoining the boiler house is to be a store for 1,000 tons of coal (about three weeks' winter supply). The floor of the store is to be above the level of the boilers, so that the coal, after being placed in it, will not have to be lifted again. A 4-ton power-hoist and raised tramway is to be provided for filling the store. Arrangements are to be made so that the coal is discharged from the store into trucks running on tramways above the level of the boilers and discharging into the hoppers of the mechanical stokers. Another tramway, on a lower level, is to be provided for the removal of the ashes, and is to carry them to the bottom of the hoist above mentioned, which will lift them to a convenient height for discharging into waggons.

In the engine house is to be a gallery containing the regulating rooms.

The design for the exterior of the building to be subject to the approval of the corporation.

The corporation to provide the site and to bring to it a suitable water supply, and to provide for the removal of the waste water.

The Traveller.

A 20-ton power-traveller to be supplied and fixed in the engine

* Mr. Swan is now making lamps of 40 and 100 candle-power (for street lighting, &c.) which can be used with the 20 candle-power lamps. They take the current of two and five 20 candle lamps respectively.

† It will be seen that this allows ample provision for maintaining 60,000 lamps all night, and a smaller number in the day, the supply being continuous.

* These dynamos are excessively strong, the revolving parts being built up of wrought-iron plate. The total weight of each dynamo is about 45 tons.

† These engines are extremely economical of coal, and are practically silent.

‡ The use of separate engines for the exciters enables the current to be regulated by varying the speed of the small engines, and without the waste which would be involved if the regulation were done by the introduction of resistance.

§ Thus, when all the 60,000 lamps are at work four dynamos and four exciters will be in use, requiring in all 6,360 I.H.-P.

|| The Telegraph Construction and Maintenance Company would prefer to do the whole of this work, and not to have it done by the corporation as at first proposed. It is included in the price given below.

Digitized by Google

room, so that it can lift any portion of the engines or dynamos that may at any time require lifting.

Regulating Apparatus and other Fittings.

The following fittings and regulating apparatus to be furnished:—

Eight photometers, 6 ammeters, 10 volt-meters, 8 registering volt-meters, 5 strophometers, 5 steam gauges, switches and slow motion levers to exciting engines.*

Suitable plug boards for varying connections of dynamos and removing defective coils.

All suitable apparatus for rapidly substituting one large dynamo for another in a circuit, and for substituting one exciter for another.

Foundations and Fixing.

All necessary foundations to be built, and all the boilers, machinery, &c., to be properly fixed.

The Mains.

The mains to consist of copper rods of not less than 96 per cent. conductivity, efficiently insulated and enclosed in iron tubes, separate tubes being provided for the line wire and for the return.

The section of the copper is to be such that when any portion is carrying the full current for the number of 20-candle Swan lamps that it is specified to carry, such current shall not exceed 1,750 amperes per square inch section of copper.

All necessary junction and testing boxes to be provided.

Laying the Mains.

The mains to be laid underground, as shown on the map sent herewith. The figures on the map are the number of lamps proposed for each house and block, but are subject to any reasonable modification, the total being kept the same. Each machine has two circuits, so the four working machines supply eight circuits in all.

There are four sets of lines (A, B, C, D) on the map, radiating from the engine house; each line represents two circuits (or four conductors).

The two circuits shown by the same line are to be connected to different machines, so that every house has half its lamps supplied from one machine, and half from another, and so that in case of any machine being temporarily stopped from any cause, no single house will be placed in darkness.

All these mains and branches to be laid and fixed, and two pairs of poles brought into each house, as shown on the plan, and all streets to be made good again.

Working Thirty Days.

As soon as all the above work is complete, and also the fixing of the lamps in the houses (or a reasonable proportion of them to be approved by the corporation), the machines to be started and a supply of electricity provided for thirty consecutive days and nights, such supply being sufficient for 60,000 lamps (or such less number as may be approved by the corporation) from sunset to sunrise and for 20,000 from sunrise to sunset, an intermission of fifteen minutes being allowed in each circuit twice between sunrise and sunset, but the intermissions in the two currents supplying any one house are never to coincide.

In case of any weakness, defect, or imperfection showing itself during these thirty days, the Telegraph Construction and Maintenance Company are to repair it. At the end of thirty days' satisfactory trial, they shall be held to have completed their undertaking. The Telegraph Construction and Maintenance Company to supply coal, oil, and labour for the trial; but the corporation to supply water—all rates and taxes chargeable on the works while in progress to be paid by the corporation.

If, at the completion of all the work except the thirty days' trial, there shall not be in the opinion of the corporation a sufficient number of lamps erected to render a satisfactory trial possible, the corporation may direct the commencement of the trial to be postponed for a period of not more than two months; but, in the event of their directing such a postponement, then (in addition to the price agreed upon) interest is to be paid by them at the rate of 5 per cent. per annum on the amount of the payment which falls due at the end of the thirty days' trial, such interest to count from the date of the completion of the work to the date of the corporation giving permission to commence the trial.† No such interest, however, shall be claimed if the Telegraph Construction and Maintenance Company have been employed to erect the lamps and internal fittings, and if the delay is caused by any fault of theirs.

General.

The whole of the work is to be finished in the most complete and careful manner.

Price.

The price to be paid by the corporation to the Telegraph Construction and Maintenance Company for the whole of the above work to be two hundred and twenty thousand pounds (£220,000).

* The ten volt-meters (two to each dynamo) enable the workman in charge of each dynamo to keep the electric pressure constant. The eight registering volt-meters (one to each circuit) inform the manager in the morning of any variation of pressure which may have taken place during the night. The strophometers show the speed of the large engines; the ammeters show the strengths of the exciting currents.

† A good trial can be obtained as soon as 15,000 lamps in all are erected, as the eight circuits can all be temporarily connected into two and attached to each one of the dynamos in turn.

Appendix.

Estimated Working Cost for 60,000 Lamps.

The following figures are given for the information and convenience of the corporation. It is believed that they are correct, but they are not in any way guaranteed:—

	Per annum.	Per annum.
All the lamps working 2,500 hours per annum.		
Depreciation and repairs (noting that ⅕ the machinery is idle)		£10,000
Coal:—		
For 6,360 H.-P. for 2,500 hours, at 2¾lbs. of coal per I.H.-P. per hour. 19,370 tons, which at *10s. per ton makes		9,685
Oil, waste and petty stores		830
Labour:—		
†Electrician's Department:—		
One chief electrician	£350	
Two assistant electricians at £150	300	
Four workmen at 26s.	270	
Engineer's department:—		
One chief engineer	350	
One assistant engineer	150	
Each shift—To each dynamo, one engine driver at 35s., one labourer at 25s., one dark room man at 30s., four dynamos at work make £18 per week, or £936 per annum. Three shifts of eight hours each ‡ (men of day shift to do all cleaning and assist in minor repairs)	2,808	
§Firemen:—		
To attend to the boilers, which are fired mechanically—		
Two chief firemen at 45s.	236	
Assistant firemen at 28s.—		
First night shift to attend to 30 boilers, 6 men	875	
Second night shift to attend to 20 boilers, 4 men		
Day shift to attend to 6 boilers, 2 men		
‖Repairing shop:—		
Two fitters at 40s. and 35s.; one labourer at 25s.	260	
Total labour		5,393
Water rate		500
Other rents, rates and taxes		500
Office expenses		500
Renewal of Swan lamps, at 2s. per 1,000 lamp-hours on 60,000 lamps for 2,500 hours		15,000
Total annual expenditure		£42,608
Cost of Gas:—		
60,000 gas jets (of 12 to 14 candle-power each), each burning five cubic feet per hour for 2,500 hours, burn 750,000,000 cubic feet, and with gas at 2s. 6d. per 1,000 cubic feet, cost		£93,750
If the consumers are charged the same for each Swan lamp as for each gas burner, this gives us		
Revenue		93,750
Expenditure		42,608
Profit		£51,142

to pay a dividend on a capital expenditure of £220,000, which is equal to 23$\frac{3}{16}$ per cent. per annum.

* Good steam coal is here supposed to be used, but the boilers specified will burn slack coal, which is cheaper.

† The labour required for repairs in the houses is not counted here as the house owners requiring it will be charged with it.

‡ Here each man will work 56 hours per week of seven days.

§ Note that with the coaling arrangements shown in the drawing of the boiler house the coal is delivered mechanically, direct from the store into the hoppers of the steam stokers.

‖ For minor repairs only. Large repairs are included in the item "Depreciation and repairs, £10,000."

Digitized by Google

If the corporation wished to make only six per cent. per annum they could supply the electricity (lamp for lamp) at the same price as gas, at less than 2s. 6d. per 1,000 cubic feet, as follows :—

6 per cent. on £220,000 =	£13,200
Working expenses.....	42,608
Required annual revenue.....	£55,808

Thus would be obtained from 60,000 gas jets burning 750,000,000 cubic feet per annum with gas at 1s. 6d. per 1,000 cubic feet.

Summarising these Results, we have

	Lamp of	Cost per hour to the Consumer.
Gas at 2s. 6d.	14 candles	·149 penny
	20 candles	·212 ,,
Electricity to pay 6 per cent., 20 candles		·090 ,,

If instead of each lamp (gas or electric) burning 2,500 hours per annum, two or three burning alternately make up the 2,500 hours, the above result will not be altered, the electricity and gas being alike supplied by meter.

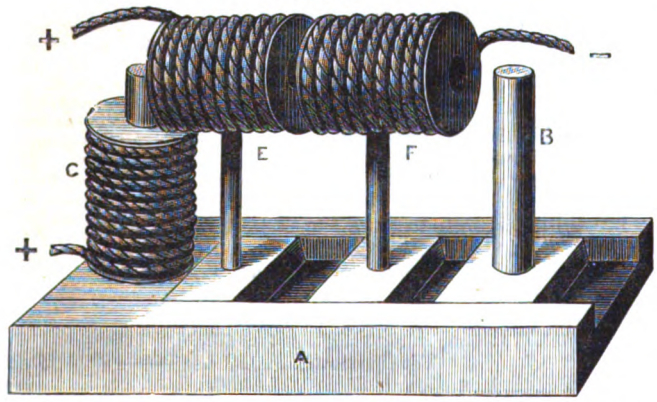
MAGNETISM.

BY JOHN T. SPRAGUE.

(CONTINUED FROM PAGE 539.)

18. *Needles for Galvanometers and Compasses* may be very well magnetised in the apparatus shown (Fig. 13), which carries out the principles just explained. A is a base of iron, with sides to form a slide frame. B is the core of an electro-magnet, mounted on an iron base, sliding on A. A similar core of C can be fixed

FIG. 13.



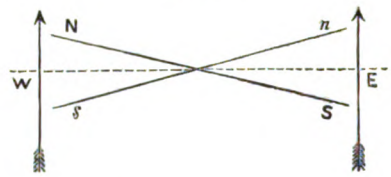
Iron base, A. Fixed electro-magnet, C. Core of sliding electro-magnet, B. E F, electro-magnets on sliding feet.

in A direct, and is shown with its coil mounted. E and F are electro-magnet coils, carried on sliding bases, so that they and B can be adjusted to the length of any bar to be magnetised. The wires of C and B are to be connected together as usual to carry a steady current. The ends + and − of E and F are similarly connected, so as to divide the current with C B. The middle ends are to be connected to a break, or one may be joined to a file, and the other run along it, so as to set up intermittent currents in this part of the system. The coils E F are made in two for the purpose of inserting mounted needles or pairs of needles.

19. *Astatic needles* are pairs with their poles in the opposite directions ; they can be magnetised in the apparatus just described by reversing the direction in which the needles are placed in E.F. If the two needles are exactly alike, and perfectly truly mounted, such a system has no directive power in the earth's field, but will place itself in obedience to any external agency, such as torsion, and would range itself at right angles to a wire between the pair, however feeble the current in the wire. It is usual to give a slight directive force by leaving one needle slightly stronger ; in any case the needles cannot long remain equal, as if one is inside a galvanometer coil, as usual, and the other outside, the inner will receive stronger magnetic impulses ; and, if unequal, the one whose position in the earth's field is reversed will lose magnetism.

20. It is commonly taught that such astatic systems will place themselves east and west, and some books furnish a very elaborate mathematical reason for this. Neither the statement nor the explanation is correct. If two needles are very closely equal they sometimes range themselves east and west, and Fig. 14 will explain the reason. The two needles are not exactly in the same plane ; the figure, of course, exaggerates the error of adjustment to exhibit the effect. N S and *n s* are the two opposed needles. Now it is evident that they produce two magnetic fields, N *s* and *n* S having the same direction as the earth's magnetic field shown by the middle arrow. Hence it is a misstatement of the facts to say that the needles place themselves east and west. The needles have no directive action because they neutralise each other, but *their external fields* unite to form two parallel fields shown by the arrows, and these fields unite with the earth's field and place themselves in the usual direction, of course carrying the

FIG. 14.



neutralised needles with them, and as an incident causing them to lie in the east and west direction.

21. *Quality of Steel.*—Some authorities say that for large magnets hardened cast steel is best ; for compound horseshoe magnets the same steel annealed at 500°, or hard shear steel ; for needles, cast steel annealed in boiling oil. Steel made of the best iron, such as Swedish, makes the best magnets ; but it is very doubtful if *cast* steel is adapted to the purpose. It is now found that the presence of about 3 per cent. of tungsten (wolfram) endows steel with high magnetic power ; this steel is manufactured at the Allevard works in France, and is now employed for high quality magnets by many makers, but it is rather costly.

Cast iron will also take permanent magnetism ; it should be of a quality containing little carbon, known as white iron, and is improved by the addition of 10 per cent. of steel ; it should be tempered or rather hardened at a high temperature, and it is not unlikely that the best process would be that known as "chilling," that is, casting in cold iron moulds. Attempts have been made to magnetise both cast iron and steel by a current passed while in the act of solidifying, but the result is to produce hollow castings. The moulds may also be placed in a powerful magnetic field, but it is very doubtful if the result would repay the trouble and expense.

By care in selection of metal, and in magnetising, bar magnets have been produced carrying 20 times their weight, and horseshoes 40 to 50 times their weight.

22. *Form and Arrangement.*—For compass needles the best form is flat, tapering from the middle to the points. For bar and horse-shoe magnets the mass of material should be divided into a number of plates not exceeding a quarter-inch in thickness, separately tempered and magnetised, and arranged with their similar poles together. They should be insulated from each other by sheet brass or cardboard, and bound together by screws or external bands of brass, and in some cases it is well to terminate the whole by pieces of very pure soft iron, shaped as desired, fitted to the end of the bars, and secured to them.

Very powerful magnets have been made of late from very thin steel plates similar to that used for clock springs, with the ends gathered into terminal blocks as just mentioned. These, which are called "Jamin's" magnets, are much used for small dynamo machines, fuze exploders, and similar apparatus.

When several bars are thus united the total force is never equal to the sum of the whole separately, because the similar poles tend to neutralise each other ; in some cases the central bars will even be reversed by this action, for which reason they should be the longest. This is the reason, together with the superior temper of the metal and more complete penetration of the magnetism, that a number of separate pieces give more power than a solid bar of the same mass, as in this the interior portions are apt to take reverse magnetism to the exterior, thus completing closed magnetic circuits, and leaving little force to be exerted on external objects.

23. *Preservation of Magnets.*—They should be carefully handled, and all jarring actions avoided ; when not in use needles should be placed in the true magnetic direction ; the same with bars ; but either may be still better preserved by placing two together with their poles reversed, and a small piece of soft iron between

Digitized by Google

them at each end. Horse-shoes should always have the keeper or armature on, and their powers may be greatly increased by hanging them up with a weight attached, which can be gradually increased. Care should be taken, however, never to violently detach the keeper, and when this is removed for use, it should be done by sliding it off across the poles, not by pulling it away.

24. The power of a magnet is influenced by its surroundings, such as neighbouring magnets and currents, and also by temperature; a strong heat demagnetises steel, and the magnetism even lowers with an ordinary rise of temperature, increasing again as temperature lowers. It is also found that a flash of lightning, even though distant, affects the magnetic force, showing how intimately connected all nature is. M. Marcel Deprez (the construction of whose galvanometers renders the question of constancy important to him) asserts that magnets do not vary in their intensity by lapse of time, and has described some interesting apparatus and experiments in proof of this; but general experience does not agree with him.

25. *The earth itself is a large magnet*, and this is the reason that the magnetic needle has an apparent directive power, because it places itself on the lines of the earth's magnetic field. Terrestrial magnetism is a subject by itself, and one of vast practical interest, but it will be treated in these articles only so far as to regard the earth as a huge magnet, and to understand that its actions are the same as those of any other magnet. The poles of the earth's magnetism are not coincident with its axis of revolution, nor are they permanently fixed; hence the *variation of the compass*, which varies according to some definite but as yet unknown law. It appears as if there were two magnetic axes (that is, two N and two S poles), which make a slow revolution around each other, while this compound axis also revolves around the polar axis of the earth in a period of about 320 years. At present the position of the magnetic poles is

North pole. Latitude 77° 50′; Longitude 63° 31′ West.
South „ „ 77° 50′; „ 116° 29′ East.

26. The *variation*, or declination, besides this general change about 7′ per year in England and now amounting to 18° 25′ to the westward and diminishing, has annual and daily small variations, due apparently to the electric currents generated in the earth by the variations of temperature.

27. The *intensity or force* is subject to similar variations, caused partly by the change of position of the poles as regards each part of the earth, which at present slowly increases the force in England, and partly by the fluctuations in the causes of magnetism itself, which probably are connected with periodical changes occurring in the sun, and the maximum and minimum periods of sun spots, and also probably with the grouping and relative distances of the planets. Irregular variations accompany displays of aurora.

The force is considered under two heads.

28. The *dip* or vertical component is the intensity of the attraction with which a perfectly balanced needle is drawn out of the horizontal line with its end dipping towards the nearest magnetic pole, where it would assume the vertical position. The practical effect is that a magnetised needle requires a counterpoise to balance this force if it is intended to rest in a horizontal plane.

29. The *horizontal intensity* is of the most importance, as in galvanometers the value of a deflection produced by a current is proportional to the horizontal intensity of the earth's pull on the needle at the place of observation, which varies from a maximum at the magnetic equator to nothing at the pole; its position of greatest intensity is in latitude 0°, longitude 101° west, where it equals dyne ·3733. At Greenwich its value was

	Dynes C.-G.-S.	Metric M.-G.-S.
1848	·1716	1·716
1873	·1791	1·791
1875	·1794	1·794
1881	·1805	1·805

An approximate formula for ascertaining the value at different parts is given by Biot as $\sqrt{1+3\sin^2\lambda}$, where λ is the magnetic latitude or inverse angular distance from the magnetic pole.

Another formula is based upon the assumption that the earth is a uniformly magnetised body, or that it acts as the magnetised field generated by a magnet at its centre; the magnetic moment, section 32, gives ·33092 × sin λ.

(TO BE CONTINUED.)

NUMBERS OF "THE ELECTRICIAN" OUT OF PRINT.—The following numbers of *The Electrician* are out of print, and cannot be supplied at the office, viz.:—Vol. 1, Nos. 3, 9, 19; Vol. 7, Nos. 8, 10, 12 to 18, 20, 21, 24 to 26; Vol. 8, 1, 3, 6 to 12, 15 to 26; Vol. 9, Nos. 2, 4, 24, 25; Vol. 10, No. 13.

ON THE INFLUENCE OF SURFACE-CONDENSED GAS UPON THE ACTION OF THE MICROPHONE.*

BY I. PROBERT AND ALFRED W. SOWARD.

One of the theories advanced to account for the action of the microphone states that the layer of air between the microphone surfaces acts as an ordinary resistance, that the effect of sonorous vibrations is to cause the carbons to approach, and to recede from, one another, and so to alter the thickness, and consequently the resistance of this interposed layer. This variation of resistance produces the variation of current essential for the reproduction of sound.

There is in physics a phenomenon known as heterogeneous adhesion, one phase of which is the surface condensation of gases. A study of this phenomenon shows that every surface exposed to a gas is coated with a condensed layer of that gas. The more readily the gas is liquefiable by pressure the greater is the quantity condensed, and in the case of the very readily liquifiable gases the exposed surface is actually coated with a layer of liquid.

Our atmosphere, as is well known, consists mainly of nitrogen, oxygen, carbon dioxide, and water vapour. Careful experiments with charcoal (a substance which, owing to its porous nature, possesses a very large surface relatively to its mass) show that the coefficients of surface condensation of these gases (that of hydrogen being taken as unity) are 3·5, 4, 15, and 80, respectively. These figures multiplied by the figures representing the proportions in which the gases exist in the air, viz., 79, 21, ·03, and, say, 1·5 give the proportions in which the substances exist in the condensed layer. They are:—Nitrogen, 276·5; oxygen, 84; carbon dioxide, ·12; and water vapour, 120. Of these four gases the first two, oxygen and nitrogen, would be condensed without liquefaction, and the effect of this condensation would be to slightly reduce the electrical conductivity of the layer, for it is known that the conductvity of a gas is reduced by condensation; the carbon dioxide would probably be liquefied, and the effect of its liquefication would be (slightly, on account of the small quantity acting) to increase the conductivity; the water vapour would certainly be liquefied, and the effect of its liquefaction would be to very considerably increase the electrical conductivity of the layer. The effect, then, of this phenomenon of surface condensation is to coat the microphonic surfaces with a layer of far better electrical conductivity than ordinary air.

In order to test the influence of this layer of condensed air upon the action of the microphone, we have lately made some experiments with the instrument in different gases. The gases used were hydrogen, carbon dioxide, wet air, and dry air; and our method of experimentation was as follows:—A microphone of a well-known pattern, consisting of a glass tube containing cylindrical carbon blocks, and having many contact surfaces, was attached to the inside of a clock case and placed in circuit with a Hughes audiometer, a Morse key, and three Leclanché cells. The carbon blocks of the microphone were pressed well together, so as to avoid as far as possible alteration of contact due to chance vibrations. A current of air, dried by passage over pumice stone soaked in strong sulphuric acid and then over peroxide of phosphorus, was urged through the microphone for half an hour. The resistance of the microphone was then measured, and the point of the audiometer scale determined at which the beating of the clock became inaudible in the telephones. A current of similarly dried hydrogen was then passed through the microphone for half an hour, and the resistance again measured and the point of silence determined in the audiometer. The experiment was next repeated with carbon dioxide, the dried gas being passed through the microphone for a similar period; and, finally, for fifteen minutes a current of air was forced through water contained in a Woulffe bottle (in order to load the air with water vapour) and then through the microphone. The resistances and points of silence in the audiometer were determined as before. Our results are expressed in the following table, and it may be noted that the scale of the audiometer was graduated 0° in the centre to 100°:—

Name of gas.	Resistance of microphone in ohms.	Point on scale of audiometer at which silence was reached.
Wet air	386	51°
Carbon dioxide	435	56°
Hydrogen	600	58°
Dry air	520	63°

It will be seen that the best result was obtained with wet air, which, calculation shows, should give a good conducting surface layer. Next in order is carbon dioxide, which, in the liquid state, is a moderate conductor. Hydrogen comes next, as would be expected, for neither it nor dry air is reducible to the liquid state by ordinary surface condensation, and the best result is to be looked for from the less condensable of the two—that is, hydrogen. The resistance of the hydrogen-charged microphone is, however, anomalous.

In order to obtain our layers of condensed gas we considered it sufficient to pass a stream of the desired gas over the microphone for some time, because it is known that when a piece of carbon charged with one gas is placed in an atmosphere of another, the two gases diffuse into one another, with a result that the carbon remains charged with a mixture in the proportions indicated by multiplying their percentage volumes by their respective condensation coefficients. In our experiments the quantity of gas passed through the microphone in any one experiment was vastly greater than the residual gas from previous experiments.

We did not attempt to rigorously exclude water in any of our experiments, for it has been shown that the last trace of water so obstinately clings to a surface that to perfectly dry a glass tube it must be raised to the softening point, and so kept for some hours, while a stream of dry air is urged through it.

In these experiments with different gases there is a possible source of error which must not be overlooked. We have elsewhere shown (*The Electrician*, Vol. X., p. 496) that the resistance of a piece of porous carbon is not

* Read before the Society of Telegraph Engineers and of Electricians on Thursday, April 12, 1883.

Digitized by Google

a constant for a given temperature, but varies with the chemical nature and with the density of the gas with which the pores of the carbon are filled. It follows from this that if a constant electromotive force be used the current flowing and the sounds obtained will be altered by any alteration in the nature of the gas absorbed in the body of the microphone irrespective of the contact surfaces. But the carbon used for our microphone had very little absorptive power, and its resistance was practically constant at constant temperature.

We think from these experiments it is fair to infer that the layer of condensed gas with which every microphone surface is covered is concerned to some extent in the regulation of microphonic action.

As bearing upon the effect of a layer of moisture we may notice the following experiment:—

A common tin canister, joined through a rheotome to one pole of a 4-cell Grove battery, and held in the hand by an insulating handle, was pressed against the ear; a wire attached to the second pole of the battery was held against the tongue. Sounds were heard corresponding to the working of the rheotome, and a burning sensation was experienced at the ear such as one might imagine would be produced by innumerable small electric discharges. Similar results were obtained with a 10-cell Daniell battery (chamber pattern). The surface of the canister, which, having been exposed to the air, was coated, as all similarly exposed surfaces are, with an invisible layer of moisture, was then well wetted. The burning sensation became more marked, but the sounds of the make and break were no longer audible. We may add that a solid brass ball, whether wet or dry, gave no sounds in this experiment.

THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.

Thursday evening, the 26th ult., was assigned to the discussion upon the several papers relating to microphonic contacts and the theory of the microphone read at the two previous meetings of this society—papers all of which have now been published in these columns. No fewer than three additional papers, however, were read on this occasion, and, consequently, the discussion proper was brief and limited. The first paper was a communication from Professor SILVANUS P. THOMPSON, in which he took exception to some portions of Mr. Shelford Bidwell's paper, chiefly relating to contacts of metal. The effects of loose contact, and of subjecting them to pressure were, Professor Thompson stated, well known ever since the early days of the telegraph, when binding screws were introduced, and when operators were instructed to make firm contacts with their working keys. In the second place Mr. Bidwell had not sufficiently investigated the range through which the current can be varied. He (Professor Thompson) had found that the available range of resistance, when metals were employed, varied with their conductivity. It was to be regretted that bismuth chiefly had been experimented upon by Mr. Bidwell, because that was, of all metals, the most unsuitable for testing their qualities as microphonic contact makers. Mr. G. S. Anders and himself had tested silver contacts in that way, and had found them not only less liable to deterioration, but more distinct than carbon, though the adjustment was more difficult because of the superior conductivity of the metal. And this was confirmed by the fact that carbons of best conductivity were best for microphones. He further pointed out that Messrs. Theiler, as well as Mr. Blake, had used metals for microphonic purposes before Mr. Munro. Reis also had used them, and although it was alleged that Reis had done so without knowing what he was doing, he, Professor Thompson, contended that Reis's instrument would transmit speech, and no carbon transmitter could do more than that.

Professor HUGHES offered a few observations to the effect that, although no doubt the theory now finding most favour for explaining the action of the microphone was correct as far as it went, it did not account for everything. For example, there was the fact first made known by a writer in the *Telegraph Journal* in 1880 that a sliding lateral contact would do as well as one of pressure—that is to say, a piece of carbon attached to the back of a diaphragm answered very well if it slided upon another carbon below it, instead of pressing against one behind it. He also stated that the microphone acted very well if you placed it in a glass of water and projected the voice upon the liquid surface. An arc theory accounted for much, and he accepted it to that extent. An electric arc had actually been made to transmit speech; but still he thought there were two classes of vibrations to be taken into account, and which had not yet been brought into harmony, the one a mechanical vibration such as resulted from the tapping of a block of wood, and the other an electrical vibration. A curious fact had come out in experiments made by Dr. Warren De la Rue and himself, namely, that with a weak power they had made a current to pass between two wires in a tube, nearly, though not quite, touching each other, whilst with a much stronger battery no current could be made to pass.

Professor AYRTON objected to the use of the term contacts in microphonic discussion, for, in reality, there were no contacts. Range as dwelt upon by Professor Silvanus Thompson had a good deal to do with the effects. The E.M.F. required was immensely greater for metals than for carbons, because the range is much less. For soft carbons much less E.M.F. was required than for hard carbons. He explained why a strong current would sometimes not pass when a small one would, by the circumstance that the energy exerted was sufficient to repel, and was expended in repelling the opposing points, and thus no current would bridge over the gap, at least none of sufficient duration to be perceived. On the whole he was led to the conclusion that microphonic elements were not in contact, and that in trying to account for their action we have to deal with an arc.

Mr. MUNRO then read a written supplement to his former paper, and argued that the objection taken by Mr. Bidwell to the metallic contacts applied to single ones, not to numerous ones such as were present in his, Mr. Munro's, gauze microphones. The new feature in this investigation was that of the repulsion of the contact points. He had illustrated this by freely suspending two carbons horizontally with their ends touching, and he now stated that when a current was sent through them they were seen, by means of a magnifying glass, to fly apart; they immediately fell together again, and were again repelled, the effect of which was that of a make and break contact, causing an incessant chatter of the telephone in circuit. Mr. Munro was understood to say, however, that metals do not appear to repel each other in this way. He also stated that a marked increase in the sound of his metal gauze microphone was produced by the approach of a magnet to their surface, diminishing perceptably as the magnet is gradually withdrawn. Lastly, he had caused to be made, and now exhibited, a microphone of his own pattern enclosed in a glass globe, the air from which had been exhausted. It acted perfectly well, and it could be regulated by means of a magnet from the exterior.

Mr. FAHIE then read a short communication, chiefly devoted to critical observations on the tables furnished in Mr. Bidwell's paper.

Mr. BIDWELL briefly replied, reminding the meeting that his paper dealt with facts the result of careful experiments; and that the criticisms directed against any theory he was supposed to be advocating were based on misapprehension. His paper was intended as a contribution of data that might assist in establishing an explanatory theory, but he had offered no theory of his own.

Mr. JAMIESON then exhibited and described a new electric current meter invented by Mr. Blyth of Glasgow; the usual votes of thanks terminating the proceedings.

WELCOME TO DR. NORVIN GREEN.

On Monday last a number of gentlemen, at the invitation of the directors of the European Atlantic Cable Companies, met to welcome Dr. Norvin Green, President of the Western Union Telegraph Company of America, now on a visit to this country. A commodious boat placed at the service of the guests started at six o'clock from the Westminster Pier for Greenwich, where, at the Ship Hotel, an excellent dinner was served. John Pender, Esq., M.P., presided, and among the guests present we noticed: William Abbott, Esq.; Arthur Anderson, Esq.: Kenneth Anderson, Esq.; G. Armitstead, Esq., M.P.; Hon. Evelyn Ashley, W. Barber, Esq.; C. H. W. Biggs, Esq.; C. Burt, Esq.; Viscount Bury, K.C.M.G.; G. Von Chauvin, Esq.; Mr. Coddington, Alexander Crum, Esq., M.P; W. S. Cunard, Esq.; Edward Dicey, Esq.; Henry Edwards, Esq., M.P.; Sir George Elliot, Bart., M.P.; William Ford, Esq.; L. Floersheim, Esq.; J. W. Fuller, Esq.; J. O. Green, Esq.; Dr. Norvin Green, J. G. Griffiths, Esq.; C. J. Gunther, Esq.; Admiral Sir Henry Keppel, G.C.B.; Hon. Mr. Keppel, M. le Comte de Lambertye, Mons. Lespinas, John Mackrell, Esq.; Mr. L. Maton, John Pender, Esq., M.P.; J. H. Puleston, Esq.; Dr. Pyle, Mons. Pouyer Quertier, M. le Marquis de Remy de Courcelles, Mons. Léon Riant, Professor Thorold Rogers, M.P.; E. M. Underdown, Esq.; Sir Hussey Vivian, Bart., M.P.; Sir Sidney Waterlow, Bart., M.P.; H. Weaver, Esq.; H. B. Weaver, Esq.; T. H. Wells, Esq.

After the toasts of "Her Majesty the Queen" and "The President of the United States" had been duly honoured,

Mr. FORD proposed "The Houses of Lords and Commons," coupled with the names of Lord Bury for the House of Lords and the Hon. Evelyn Ashley for the House of Commons. He said: I have been honoured with a request to propose the next toast. I do so with alacrity, because, according to the prophets of evil, the establishments forming part of the constitution of the country will soon cease to exist. Indeed, it may be that at the present moment a defeated majority may have succeeded in un-Christianising the House of Commons and rendering it less worthy of the respect of the people of this country. But, fortunately, I have to ask you to honour the House of Lords and the House of Commons as they are at present. I beg to propose "The Lords and Commons as at present constituted," coupled with those honourable names of Bury and Ashley.

The toast having been duly honoured.

Lord BURY, in response, said: My hon. friend, Mr. Ford, has proposed this toast with an invitation which is rather ominous. He proposed the Houses of Parliament as at present constituted. Well, I have always heard that there is a proverb that threatened men live long, and although I have heard that the House of Lords is to be abolished, I still think that it has a great deal of good work to do, and that it is not yet awhile to be abolished. Pending that day I return thanks for the kind way in which you have received the toast of the House of Lords. But when the evil day does come, and when the House of Lords is abolished, I made up my mind from the moment I heard the speech of my hon. friend that I shall apply for the post of electrician to the companies under the direction of my hon. friend on my right (Mr. Pender), so that I may be ready for the evil day when it comes [laughter]. I am a very good electrician, and Mr. Puleston knows that I am well qualified for that post. There is here at this table Mr. Munchbare who was my instructor in electricity, and he will tell you whether I am competent to test a cable, and many is the time that we have tested together in the pleasant room in which we are now sitting [laughter]. I am surrounded by the Nestors of electric telegraphy. I have no doubt that my hon. friend on my right has the thousand pound share which he subscribed, and which laid a cable in 1857 or 1858 not 100 yards from where we are sitting on the other side of the river. That cable was successful, and I may say that my hon. friend on my left (Sir George Elliot) was also a member of that association. That cable was a short lived cable, but it lived long enough to flash across the Atlantic two most important messages—one relating to the despatch of a British regiment, and the other relating to the crew of a wrecked British ship [hear, hear]. Those were the days when we were adventurers in the attempt to bridge the Atlantic by connecting England and America. I remember in those days it was thought a wonderful thing for the cable to be laid, and still more that one message should be passed: now messages increase day by day, and my hon. friend, the chairman, will give you extraordinary statistics which speak of the increasing number of messages across the Atlantic, and which unite the two nations in a bond of brotherhood impossible to be dissolved. From that day to this—from 1857-8 until now, as Mr. Pender has justly said, a vast work has been performed in telegraphy. Those whom Mr. Pender has brought around this hospitable board are the men who have done the work, and under these circumstances whether the House of Lords live long or live only a short time, I feel it an honour in responding to the toast of the House of Lords as they at present exist. [cheers].

The Hon. EVELYN ASHLEY, M.P., in replying for the House of Commons, said: One of the minor drawbacks in the otherwise great honour of

Digitized by Google

being connected with an Administration is that we are called upon, in the presence of other and much older members of the House of Commons, who are fully as well entitled, if not more so, to return thanks for that House. The proposer of this toast has invited us to sing an elegy to a dying institution; but I am in no mood to do any such thing. I believe that though the difficulties of the House of Commons have been great, are great, and will be great in the future—that as long as the Anglo-Saxon race lasts representative institutions must last, and the House of Commons amongst other representative institutions. Now, the House of Lords has been very adequately responded for by my noble friend; and I would only remark with reference to what he says, that there is a great deal of electricity in the House of Lords; and there is no doubt that from time to time, with all their great merits, they do give us electric shocks in the Lower House; and what we must try to devise is some non-conductor to come between the two Houses, so that the effect may not be fatal to either House [laughter]. That is my fervent prayer and hope. Now, gentlemen, before I sit down I thank you for drinking the health of the House of Commons in so warm and enthusiastic a manner. I would just say, with reference to the general question of electrical communication, that though I have not that knowledge which the chairman has, I may say, as representing a department of some importance in this country, that I feel how impossible it would be, without the great electrical discovery of the present century, for the colonies of this country to be managed successfully. There is no doubt that evils arise from panic, scares, and electric messages sent more with sensation than truth, but the antidote is ready (except when the wire breaks, as Mr. Pender's did the other day at Zanzibar, but it was soon repaired), and we soon apply it. So far as the Colonial Office is concerned, they feel great gratitude for the discovery and the progress of electrical science throughout the world [cheers].

The CHAIRMAN then rose and proposed the toast of the evening, "Dr. Norvin Green and the Western Union Telegraph Company of America." He said: The toast that I have to propose now is the toast of the evening. But before I submit that toast to you, I beg to state that on account of indisposition there are several gentlemen absent this evening who would otherwise have been present. I refer to Lord Monck, Chairman of the Anglo-American Company, the Marquis of Tweeddale, a director of that company, Sir Daniel Gooch, also a director of that company, and to Sir James Anderson, also a director of that company, and whose name is so honourably associated with telegraphic enterprise. We have met here this evening, gentlemen, to do honour and to give a hearty welcome to my friend, Dr. Norvin Green [cheers]. This is the doctor's first visit to this country. It is the only thing that I have to find fault with the doctor for; but he has told me that for a long period of time he has looked forward to visiting England. He desired to come to England to find out something of the land from which he is an olive branch; for, gentlemen, in my experience of American travel, I find some of the most distinguished men there who love to look back to the old country, and to find that they are sprung from a noble root. The doctor is one of those distinguished men; and England is just as proud to have him as one of the branches as he is proud of claiming that his root was in England [hear, hear]. Gentlemen, the name of Dr. Green, as President of the Western Union Telegraph Company, of the United States, is a household word there. No man is more honoured than Dr. Green is in America. He fills the position which he occupies with very great credit and honour to himself. He has secured the confidence of the American people; and I can tell you that the position that he does occupy is one which requires not only the highest administrative ability, but, as president of that vast (I can scarcely find a word to express the omnipresence of the system over which he presides) undertaking, I say it requires not only high administrative ability, but the most unimpeachable honour [cheers]. Gentlemen, I think it is always well when speaking on an occasion like this that one should justify the opinion that you have formed and which you give of the man—I mean by statistics. These statistics apply to the institution over which he presides, and often—so very often as I have looked at telegraphic statistics—I have never been more struck than when I apply them to the systems of telegraphy in America. Let me put them before you, because it is well to have them in your mind. As I have mentioned, Dr. Green presides over a vast undertaking—a company with a capital of eighty millions of dollars. It has 13,000 stations scattered all over America; there are 20,000 *employés*; they have 150,000 miles of poles, and of wire on those poles 425,000 miles. There is no part either in the States or Canada where there is not a Western Union Station. Even in the very confines of the Indian reservation I found when travelling there the little blue sign of the Western Union Company. I may tell you that the car in which I was travelling was stopped by a little white flag, and a telegram was handed to me there; that telegram conveyed to me an evidence of the thorough organisation of the Western Union system; for when I left New York I was told, "You shall have every information in the shortest space of time." That telegram conveyed to me, about eleven o'clock in the day, news of Sir Garnet Wolseley's successful victory at Tel-el-Kebir. I had only time to reply congratulating him upon that victory, and I was told afterwards by Sir Garnet Wolseley that before the sun had set he had my answer [cheers]. Now, I say that that is a wonderful tale to tell. I found at every point we stopped at that this system, which I have already stated seemed to me to be omnipresent, showed that the progress of the Western Union Company was most marked. In 1866 there were 75,000 miles of wire and 2,250 offices. At the present time, as I have said, they have 425,000 miles of wire, 13,000 offices, and 20,000 *employés*. In 1866 the profits of the Company were little over two millions and a half of dollars. Now they are something like eight millions of dollars. The Company pays its shareholders a dividend of 7 per cent.; a share is worth something over 12 per cent.; but like prudent men they pass the difference between 7 per cent. and 12 per cent. to the reserve. Now, gentlemen, in these days of telegraphic progress (because, after all, telegraphy has, perhaps, revolutionised the world both politically, socially, and commercially to a greater degree than we have realised; and I know that statesmen, leading statesmen, have not yet realised the importance of telegraphy; it takes a long time to realise it), this system has been carried on with quiet but dogged perseverance, and there has been nothing to stop it. There have been no obstacles that have not been overcome, and the result is now that I believe telegraphy has brought the world more together, into a more homogeneous mass, than people have any idea of. And let me say that the object of telegraphy is this—to establish among the nations of the world peace and goodwill. That is the mission of telegraphy; and I believe it will have greater influence in accomplishing that end than anything that has been produced in the present century. Just let me say one word more. We look upon the great progress in telegraphy, but we measure that progress in telegraphy just as an evidence of the progress of trade. There is no transaction of any importance that takes place with China, New Zealand, Australia, Japan, India—in fact, there is no important commercial transaction that does not involve a telegram. It shows you what an influence telegraphy is having upon the world—and where would the world stand at the present moment if telegraphy were to cease [hear, hear]. Mr. Evelyn Ashley very properly said just now that the telegraph broke the other day the connection between this country and South Africa at a critical time. It was unfortunate: and in a very short period I know the anxiety which arose in the particular office over which the hon. gentleman presides. I am sorry to say that this morning it again broke down, but I am equally confident from my long experience of telegraphy that within two days it will be restored. I may tell you that when telegraphy, and submarine telegraphy particularly, was first established, there was an idea that a cable once laid in the bottom of the sea could not be recovered. That is not so. We are now as capable of repairing submarine cables at the bottom of the sea as we are of repairing a railway when an accident occurs. It is exercising an influence which we, who know something of that influence, hope to see have its effect upon those great men who lead the world and cause them to acknowledge that it is one of those elements by which they have been able to direct and guide the affairs of this country in a satisfactory way. Gentlemen, in speaking of America, in speaking of my friend, Dr. Green, I have to say that they have got a magnificent system there. We have connected that system with this country; and when I think of the pleasant two months that I spent last autumn, when I saw that country which has yet unoccupied thousands and tens of thousands of acres—when I think of the thousands and tens of thousands that are pouring into that country year after year, I have no hesitation in my mind as to what the future of America is to be, and of the benefits which that telegraphic system must confer upon the American community, and of the progress which must come from those people who go there in tens of thousands, because they will not only become producers, but they must become consumers as well; and the telegraph, as I have said, being an important element in every transaction, whether political, commercial, or social, that the progress that is likely to attend the telegraphic systems in America, as well as all over the world, is almost beyond what we can foresee or prophecy [hear, hear], and, therefore, gentlemen, I beg to ask you to drink the health of Dr. Norvin Green, who presides over that institution which is benefiting America so largely. He is administering it with great wisdom and great ability, and I only hope that he may be long spared to fill the position which he now occupies so wisely and so well [cheers].

The toast having been cordially received.

Dr. NORVIN GREEN rose to respond amidst renewed cheering. He said: Gentlemen, the only feeling that I have is an overwhelming sense of the distinguished honours you have paid to me. After several days of rocking on the ocean, which was not very agreeable, I received a welcome to the old country from my friend, Mr. Pender. I found the old country, indeed, an old but not a finished one. You are a progressive people. Old as you are, you are making advances and new improvements day by day; I find that some things are growing faster than even in our own country. One of the things that I have heard about London was that it was the place above all others where one lost his individuality and had all the conceit taken out of him. I presume the exception only proves the rule, and I find myself more conceited than ever I was before. Looking out here on the change of scene, viewing the old river which has become classic, seeing the shifting scenes, like a panorama, so different from what we have in the western world, I have been trying to ignore the embarrassing position that I occupy as the particular guest of the directors of the European cables; and it is not particularly comfortable to a modest man, and a plain business man not accustomed to such things. I look across the table and against the window, and I see the word "Welcome." This comes from the representatives of the telegraphy of the three leading nations of the earth, foremost in literature, arts, and sciences, and especially in the front van of civil and religious liberty. I find there intertwined and lapping each other the European and American cables—I find them working together in harmonious action for the common good and the common profit. I conclude, therefore, that there is not so much individuality in this country; but I am more fortunate than deserving because I happen to represent the large institution of which my friend has so kindly spoken. I am lucky, indeed, to be the representative of this division of our growing institutions. It is true I have long looked forward to, and hoped to visit the country of my ancestors, and always in contradistinction to our German friends who speak of the Fatherland I have had a thrilling sensation when any one spoke of the mother country [cheers]. This is the mother country—it is our mother country. In every State of the Union except one, where they have their code acquired from the French system, your common law is the controlling and governing law, unless modified by special statutes. The Law Courts have the same practice as our courts. Your Bill of Rights and your statutes as to personal liberties and personal properties govern our courts of jurisprudence. Some of our legislators, when they can, occasionally attempt to improve upon these institutions [laughter]. Whether these improvements are effected or not it is not for me to say. I have only to say to you that I am totally unequal to find language to express my sense of the distinguished honour which you have done me, and I must return you my sincere thanks for this mark of your approbation. As to the interest which I represent, some of its progress has been depicted by my friend, Mr. Pender. Some gentleman spoke of the length of time which it took the sun to rise on the British dominion—and I believe that it never sets on it; but it takes nearly nine hours for the sun to rise on our telegraph system [laughter]. It has been accomplished by publishing in Shanghai the quotations at the close of business at 3 o'clock in New York. We claim to be doing the best telegraph service that is being done anywhere. You are doing a good service here. I have had some city correspondence which I would not undertake to beat in our city. A gentleman in our office sends me an occasional telegram, and I must say,

Digitized by Google

that your service in this country is good. But we have connected the wires of the Chicago Board of Trade with the Produce Exchange, a corresponding organisation in New York, and it is an every day practice for a man to step to the counter of our telegraph office and to send his telegram to Chicago, some 1,050 miles, and to receive an answer before he leaves the counter [hear, hear]. Now, whatever you may say as to telegraph competition, I hold that time is our great competitor; and just as we can overcome time we can increase our business. The business between New York and London would be doubled, perhaps quadrupled, if you could get an answer within an hour. The business between New York and Chicago has been doubled and trebled by the improved service; and just as you can overcome time you can improve the telegraph business [hear, hear], so that I was very favourably struck by the project suggested by my friend, the chairman, of establishing in London an evening exchange, with hours corresponding to the morning hours of our exchange in New York, for the purpose of dealing in American securities, and where the two exchanges could meet each other to receive answers while standing at the counter at Chicago. I have not the slightest doubt that it will be done. There will in consequence be an immense increase of the telegraphic business; and not only so, but it will result in the postal arrangements between the two countries being much improved, and in strengthening the bonds of commerce, which no disputes among politicians can sever. Gentlemen, I am not a speech maker. I desire, in conclusion, to advert to the great stride in modern progress which is annihilating time and space, and which is establishing closer relations between all counties and this great centre of trade and commerce of the whole civilised world. That stride was the spanning of the Atlantic with a telegraph cable, the greatest work of modern times; and there was a feature in that that always impressed me as a part of the progress of the age, that when the first cable was laid, and when in 1866 they effected the successful landing, they went out on the trackless ocean, and, according to the date of the log of the ship, by the advance of nautical science, they picked the cable up, spliced it, and laid it down again. But even after they had laid the cable they had to invent the way to work it. None of the systems known to telegraphy at that time could approach it with any degree of success or satisfaction. We got what we call electrical impulses, and that was all. But then came the cable instrument, which enabled us to work ocean cables with almost the same facility as a land line, but not quite so rapidly; so that the ingenuity of our electrical corps seems to have been equal to the immediate wants. In the progress of electrical science they soon learnt to measure the exact distance at which the current was lost, and they could locate it within a few yards, and send the ship to pick up and splice the cable. These are wonderful achievements in this modern age, and they all result from the necessity of working the Atlantic cable. That cable was a great work, and did more to annihilate time and space, to facilitate commercial transactions, and to bind the political interests of different countries together than any step of progress that has been made in modern times. In the war of 1812 the battle of New Orleans was fought, and there were some 700 or 800 men killed, including General Pakenham, whose body was pickled and brought back home. Well, that battle was fought 15 days after the peace of Ghent, If we had then had the telegraph system no such battle would have been fought, and Andrew Jackson, the victorious General, would never have been made President of the United States. I give you "The Atlantic Cable Companies," coupled with the name of Mr. John Pender, M.P., for it was his pluck and faith in the undertaking which induced him to lend his money, thus saving an enterprise which would otherwise have been given up.

The toast was very cordially received.

Mr. PENDER, M.P., in reply, said: Dr. Norvin Green has associated my name with the Atlantic telegraph enterprise. My friends of the Anglo-American Company and the French and New York Companies have been kind enough to put me in the front place this evening to reply for the United Companies. The company which I represent has only one cable; the Anglo-American Company has four cables. Our French friends and our other excellent friends have only one cable; and the American Company has but two cables. Gentlemen, I have been a man of peace all my life. I found all those companies at one time competing. I thought that the true policy, not only for the world who would enjoy this telegraph system, but for the companies themselves, was that there should be unity of action and harmony between them. I think I may claim the credit of taking a prominent part in bringing about that harmony which prevails at present [cheers]; and, in bringing about that harmony, I am quite sure that I did not injure those great and public interests which ought always to be considered wherever any combination takes place. I believe at the present moment that you have got a very much better telegraphic system than you possibly could have had if those four or five companies had been all competing and destroying one another. But I have another claim to reply to the toast of the Atlantic Telegraph Cables, and that is that I believe I was one of the very few—I think that Sir George Elliot was amongst us—when Mr. Cyrus Field came over from America with an idea that it was possible to span the Atlantic by a wire to take the matter up. I found some men shaking their heads and saying, "Oh! that is an impossibility." One of the great statesmen of the present day told me at a little party that I had gathered together—and I rather think my friend Sir George Elliot was present at that party—that he had never met at a table twelve men who, in their individual capacity, were men of such great shrewdness, great sense, and great engineering capacity. If I were to name those gentlemen, some of you would be perfectly astonished. Many of them are living to-day and are occupying the highest positions, and they were all in earnest, I believe, in the undertaking; but this great statesman replied to me, when I asked him to associate his name with what I believed would be a wonderful success, and would be one of the great bonds of progress in the century in which we live, "I have met many clever men; but never met so many men who were so mad on one point" [laughter]. The idea of laying a line at the bottom of the sea, and expecting to get money out of it, seemed to him to be a most impracticable thing. Now some few years have elapsed since this thing was first commenced, and what has been the result? Instead of one cable, we have got eight cables; but let me refer just for one moment to Mr. Cyrus Field. That gentleman will always be associated with the Atlantic cable; but there was another man—a good old man and a great philanthropist, who made his mark in America perhaps more than any man could possibly do in his life time. I speak of old Mr. Peter Cooper, who died the other day. He was the man who took Cyrus Field by the hand and gave him the money to carry out the idea which was carried out so successfully, and which has now so much influence on the world. I say that this idea, and I am proud to say it, sprang from America. We took it up manfully and willingly here, and it has been a success, perhaps beyond what was ever anticipated for an element which has done more for our progress than anything else in the present century. Let me give the figures—and then I have done—as to the submarine cables. In 15 years we have put £32,000,000 of money into the bottom of the sea; the mileage is 82,000 miles, and the revenue about £3,300,000. All this, as I say, has been accomplished in a very short space of time. I refer to the advantage which this telegraph system has been to commerce. Commerce is the root of all progress. Our first cable cost £5,000,000, and unless that had been a marked success, and unless commerce had demanded it, we would not have had eight cables at present. In fact ten cables have been laid, and eight cables are now living at the present moment in perfect harmony. We are to-day a united company. I believe we are doing great service to the world. We have met here to do honour to our worthy colleague, who has come over to visit us [cheers]. I have to thank you for the honour you have done me.

M. POUYER QUERTIER, who was received with loud cheers, and who spoke in French, then gave "The Progress of Telegraphy throughout the World, coupled with the name of Sir George Elliot, M.P."

Sir GEORGE ELLIOT, M.P.: I have to thank you very much indeed for the handsome way in which you have received my name in connection with the extension of telegraphs over the world. At this late hour I do not intend to occupy much of your time. At the same time I cannot help feeling proud at having my name associated with the toast given in the French language, and in connection with a subject which has always been so very interesting to me. It is quite true that I do not feel any degree of modesty in letting it be known that from the very earliest time I have been connected with submarine telegraphy. I see the place beyond me (the Telegraph and Maintenance Company's works) where most of those cables have been manufactured. Some thirty-one years ago I had a most excellent partner. At that time he did not believe in submarine telegraphy, and simply as a partner I insisted upon having it done in a humble place called Sunderland, in the north of England, and the machinery is still there, where I made the first cable that was ever made, not with partnership money, but with my own. We made some of the largest telegraph cables, and the last one we made was from Malta to Alexandria. Now, I will tell you a little incident, which may strike you as having a bearing upon our meeting to-night. About twenty-five years ago I had obtained a concession from the Austrian Government from Ragusa to Alexandria. I had the concession for this cable, and it was necessary to have the co-operation of the English Government from Crete to Alexandria. I went as a deputation to wait upon our present Prime Minister, Mr. Gladstone, at his own house. I was urging upon the Prime Minister that England ought to have this thing completed as a route to Austria, and that there ought to be some arrangement come to. I recollect very well the remark made by that statesman. Just let me say that I have a very great admiration for Mr. Gladstone, although I do not always vote with him, but the right hon. gentleman said to me: "We have far too many telegraphs, we do not want to be disturbed both night and day."

After the CHAIRMAN had proposed "Our Guests," and Mr. PULESTON, M.P., replied, the company broke up, and returned to town by special train.

THE INDO-EUROPEAN TELEGRAPH COMPANY (LIMITED).

The sixteenth ordinary general meeting of the members of this Company was held at the City Terminus Hotel, Cannon-street, on Monday, the 30th ult.

The MANAGING DIRECTOR (Mr. W. Andrews) having read the notice convening the meeting, the seal was affixed to the register of shareholders, and the report of the directors was taken as read. It stated, *inter alia*, that there was a balance of £28,787 to be dealt with, "and the directors propose the declaration of a dividend for the last six months of 17s. 6d. per share, making, with the interim dividend already paid, 6 per cent. for the year, and a bonus of 15s. per share, both free of income-tax, making in all 9 per cent. for the year. The balance of £1,162 will be carried to the credit of 1883. The Company has leased from the Post Office a special wire from its central office in London to Manchester and Liverpool, in which places offices of the Company were established and opened in the autumn of 1882. The maintenance by the Company of its own lines is working satisfactorily."

The CHAIRMAN said: Gentlemen, the report is a little longer than usual, but I am happy to say that that is not, as long reports usually are, an indication of coming disaster. I have generally observed that long reports are usually intended to explain deficits. In our case there is something very much more satisfactory. We made £118,000 in the past year, against £101,000, in round figures, in the previous year. That considerable increase of revenue was due, as we state in the report, entirely to the war in Egypt. During that war the wires of our friends, the Eastern Company, were totally cut down and destroyed for some months, and it therefore fell on us to conduct the entire telegraphic communication between England and India, trans-India, including China, and the Cape of Good Hope and Southern Africa—a province lying entirely out of our ordinary beat—and, strange to say, the urgencies of the case were such that a great many communications for Egypt itself were transmitted by us through India—*viâ* India to Egypt. That was a singular instance of the great value of telegraphic communication. I am happy to state that that work, the whole telegraphic business of the country, was carried out without hitch or break, or any slackness or difficulty. The extra work done was actually more than double that which we had done in the year before, although we have not derived the entire profit of all that extra work, consequent on our joint-purse arrangement with the Eastern Company—an arrangement which has proved very beneficial for them, as it has also proved very beneficial to us in past times, and may do so again. But this enormous increase of work—as I have stated, more than double—was done

Digitized by Google

with an increase of less than 1½ per cent. in the total amount paid for salaries and wages in the preceding year. That is a strong and an additional instance of the value of telegraphic communication, showing how much may be done when once the plant and establishment are there, and provided also that both the plant and establishment are good of their kind and well managed; and I may say, without exulting too much on the part of the directors, that the business was very well managed. I say that because the chief person who has established that excellent management, who saw to our plant, who trained our staff so that when the time and need came we should be able to work efficiently, was my friend Mr. Andrews. In alluding to the dividend we are now about to propose to you, I might say that, although it is a very reasonably handsome dividend, the fact is that up to the present time, if you take the average of dividends we have declared since the first establishment of our Company, you will find that they have been under 4 per cent., so that in point of fact, though 9 per cent. is a very good thing, the average outcome of the affair up to the present time is not as much as we trust in a few years we shall be able to show it can do and has done. Among other items we allude to in the report we state that we have purchased a large quantity of stores and plant from the Messrs. Siemens. It is a sort of difficult operation to purchase stores and see that they are all of the proper kind when they are spread over such enormous distances as was the case in this instance—lines extending through Germany and Russia and very many hundred miles. This work was simplified by the excellent arrangements made by Messrs. Siemens, who, of their own accord, set aside all obsolete and decaying material, and handed over such good working stuff as we were only too glad to take, for you must all be well aware that a large amount of spare stores is absolutely necessary to continue the work of the Company's line of telegraphs. We have taken over this enormous amount of stores without let or hindrance; without any litigious spirit, and leaving, I hope and believe, good feeling between both parties. A matter of satisfaction I have to mention is the renewal of the Persian concession for ten years. Some difficulty was apprehended about that. It has taken considerable time to bring about, but it has at last been conceded, and on favourable terms, so our concession runs now with all the different countries connected with the line for the full period of thirty-five years. I see no particular reason why at the end of that time it may not be renewed still further. We now come to a matter which I know has puzzled a great number of the shareholders—that which is called the Persian debt. You find it referred to at the foot of the accounts under the head suspense account. The difficulty connected with this matter is in reality very small, if you will only take the trouble to go into it. I will endeavour to give you an idea of what the Persian debt is. The line through Persia, which necessarily connects our line through Germany, Russia, and the East, was constructed for the Persian Government by the Indian Government, and the cost, £47,000 odd, was, after many arrangements between the three parties—the Persian Government, the Indian Government, and ourselves—finally arranged to be paid by Persia to India in the following manner:—First, we agreed to pay a portion of the tribute, or royalty, due from us to Persia, instead of paying it to Persia to pay it annually to the Indian Government. That is, or when the last is paid will amount to, about £23,000 out of the £47,000. It was a matter of no concern to us whether we paid it to the Persian or the Indian Government—the money would have to be paid, anyhow. The balance of this amount, however, we agreed should be deducted from our profit of the line, and paid over to the Indian Government, and the Persian Government on their behalf stated that when this was paid off we might go on deducting the amount year by year from the tribute payable to them till we had recouped ourselves. In the year 1874 we had paid a large amount out of our profits, £9,000. We were then, unfortunately, in a very sad state of impecuniosity. We found it very difficult indeed to keep up these payments, and the Indian Government very obligingly deferred exacting the remaining sum from us till we were in better circumstances. Last year they claimed performance of the agreement, and we handed over to them the amount of profit made on the Persian line, and which you find here in the return, amounting to £6,416. There still remains a sum of about £5,700 payable, which, no doubt, will be paid out of the profits of the present year, and with that payment our payments will come to an end, and thereafter, for the next eleven years, we shall recoup ourselves by the payment of nearly £2,000 a year until the whole of our advances on behalf of Persia have been paid off. We shall thus commence, from the year 1884, to be actually in receipt of nearly £2,000 a year for eleven years more than we have hitherto been receiving. We therefore thought that that was payment in the nature of reserve. I am afraid I have not made myself thoroughly intelligible to some, but if any gentleman here is such a glutton for figures that he is very desirous to see the minutiæ of this statement, if he will only apply to our excellent, efficient, and courteous accountant I am quite sure he will receive from that gentleman sufficient to satisfy the most rabid appetite for figures, and to explain up to the last farthing how this complicated account has been made out. Among other matters we have to refer to the cable conference at Paris. When I addressed you last year I had to speak in somewhat despondent tones of the delay and damage we had met owing to the injuries inflicted on submarine cables. The Government at last, after some pressure, took up the subject, and on communicating with foreign Governments a conference was held at Paris, and sundry agreements were there come to which we trust will be fully carried out, and which we hope will put an end substantially to all the various causes of complaint. I have only further to mention that you will see that in one way or another we carry rather more than usual to our reserve fund this year. We have £5,000 of actual cash payment, as it were, but we have other sums in the nature of a reserve. There are the stores and freehold buildings taken over from Messrs. Siemens. Instead of spreading their payment over a period of years, we thought it desirable in your interests that it should be paid off at once. It is part of the policy we have always adopted, since we have had the means of doing it, of paying the cost of everything that has occurred in the year, so as to leave a free and clear balance-sheet. I think you will admit that the value of our property in the market at the present day justifies the course we have hitherto taken with your sanction, and which we now hope to follow in this particular course with your sanction. The shares now stand at a very high figure because we have paid sums as they have fallen due, and because we have instituted a reserve fund, which I hope and trust yet to raise to a very much higher figure. I have no further remarks to make except to reply to any question which any shareholder may ask. I now move "That the report and statement of accounts be received and adopted."

Mr. H. WEAVER seconded the motion, which was carried unanimously.

The CHAIRMAN next moved the payment of the dividend and bonus recommended.

Mr. J. HERBERT TRITTON seconded the motion, and it was carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. C. W. EARLE, Major General G. B. Tremenhere, R.E., and Mr. Tritton, the retiring directors, were re-elected, as were also the auditors, Messrs. C. F. Kemp, Ford, and Co.

Major WOOD then moved a vote of thanks to the chairman and directors, and observed that it must have been most gratifying to the shareholders to have heard such a statement of their affairs as had been placed before them.

Mr. WILLIAM PAYTON seconded the motion, and it was carried unanimously.

The CHAIRMAN having briefly acknowledged the vote, the proceedings terminated.

THE NEW MATERIAL

or ENGINEERS (Sanitary and Hydraulic), ELECTRICIANS, AXLE MAKERS, BRASSFOUNDERS, PUMP MAKERS, RAILWAY COMPANIES, CARRIAGE and WAGGON BUILDERS, &c.

SUBSTITUTE FOR LEATHER, RUBBER, AND PERCHA.

It is unequalled for Washers of all kinds, Hot and Cold Water Packings and Plumbers' uses generally, Insulators, &c.

THE PATENT VULCANISED FIBRE

Is supplied in Sheets from 1-32in. to 1in. in thickness, and in two qualities: Flexible, 2s. per lb.; Hard, 2s. 3d. per lb.

MOSSES & MITCHELL, 68, 69, 70 & 71, CHISWELL ST., LONDON, E.C.

IMPORTANT TO TELEGRAPH COMPANIES.

SOAPS AND DISINFECTANTS

For Use at Home and Foreign Stations.

"THE MANAGING DIRECTOR, THE SANITAS COMPANY (LIMITED). "February 4th, 1880.
"We have now for more than a year been using your SANITAS soap and disinfectants in our ships, as well as at our stations, and find it greatly appreciated, more especially at tropical places."

"London, 15th November, 1880.
"I think it right to inform you that our Superintendent at Mozambique says:—'I use the much-prized "SANITAS" freely, and feel perfectly safe wherever I sprinkle it.' "JAMES ANDERSON, Managing Director, Eastern Telegraph Company (Limited), 65, Old Broad-street, E.C."

SANITAS DISINFECTING FLUID, POWDER and SOAPS.

SANITAS Fluid is Colourless, Fragrant, Non-Poisonous, and gives no stain.

THE SANITAS DISINFECTANTS ARE USED BY 600 PUBLIC HEALTH BODIES.

Samples and Prices on application to the SANITAS COMPANY, Limited, BETHNAL GREEN, E.

IN the HIGH COURT of JUSTICE, CHANCERY DIVISION.

IN the MATTER of THE COMPANIES' ACTS, 1862 and 1867, and IN the MATTER of the PHŒNIX ELECTRIC LIGHT and POWER COMPANY (Limited).

The Creditors of the above-named Company are required on or before the 10th day of May, 1883, to send their names and addresses, and the particulars of their debts or claims, and the names and addresses of their solicitors (if any) to HENRY BISHOP, of 41, Coleman-street, in the City of London, the liquidator of the said Company, and if so required by notice in writing from the said liquidator, are by their solicitors to come in and prove their said debts or claims at the chambers of Mr. Justice Pearson, at the Royal Courts of Justice, Strand, in the county of Middlesex, at such time as shall be specified in such notice, or in default thereof they will be excluded from the benefit of any distribution made before such debts are proved.

Wednesday, the 23rd May, 1883, at 12 o'clock at noon, at the said chambers, is appointed for hearing and adjudicating upon the debts and claims.

Dated this 11th day of April, 1883. E. W. WALKER, Chief Clerk.

Freshfields and Williams, 5, Bank-buildings, London, E.C., Solicitors for the Liquidator.

JOURNAL of the SOCIETY of TELEGRAPH ENGINEERS and of ELECTRICIANS.

Edited by Professor AYRTON, F.R.S.

No. 47 contains Illustrated Articles on:—
"THE MEASUREMENT of ELECTRICITY for COMMERCIAL PURPOSES," by J. SHOOLBRED.
"NEW TELEPHONE TRANSMITTERS," by J. MUNRO.
Together with original communications and abstracts from foreign periodicals.
Price Three Shillings.
E. and F. N. SPON, 16, Charing Cross.

FAURE-SELLON-VOLCKMAR ACCUMULATORS.

On and after 1st January, 1883,
THE
ELECTRICAL POWER STORAGE COMPANY
(Limited),
4, Great Winchester-street Buildings, E.C.,
will be prepared to supply
FAURE-SELLON-VOLCKMAR ACCUMULATORS.
Which can be used in conjunction with any Incandescent Lamp or Electrical system, and afford the only reliable and economical means of Lighting Private Houses, Hotels, Theatres, Ships, Railway Carriages, &c., by Electricity.
Particulars and prices post free on application.

DYNAMO for SALE, lights six 20 c.-p. lamps, or one arc of 250 c.-p. £8. Plating dynamo, £10. Other sizes and parts and castings equally cheap.
OPPERMANN BROS, 172, St. John-street, E.C.

FACTORY and WATERSIDE PREMISES to be LET, or the LEASE, at £200 per annum rent, to be SOLD. First class premises, with a frontage of about 40ft. to the canal, and 40ft. on the other side to the road. Depth about 90ft., ground floor of factory, with two floors above, 18ft. by 8ft. Steam power on the premises, to be taken at a valuation. Situate close to King's Cross. Apply to the SECRETARY of the London General Cab Company, 68, York-road, King's Cross, N.

CARBONS.—For all kinds of ELECTRIC LIGHT, Leclanché, Bunsen, and Grenet Batteries, Telephones, &c.
The best, cheapest, and most reliable for every kind of Lamp.
Carbons of any size, shape, and of every description manufactured to order at the shortest notice.
JAMES W. COLUMBINE,
2, Carlisle-street, Soho-square, W.

H. NEWBOLD,
Experimental Glassblower,
25, CALTHORPE STREET, W.C.
Mercurial Exhaust Pump & Vacuum Tube Maker.
INCANDESCENT LAMPS, &c.
STRICT ATTENTION PAID TO DRAWINGS AND DESIGNS.

SOMETHING QUITE NEW.
THE INSULITE ELECTRIC BATTERY AND BELL.
PATENTED AND REGISTERED.
Ready for use, sealed, portable, lasting, clean, convenient, and safe.
For HOUSE BELLS, ALARMS, SHOP CALLS, SICK ROOMS.
PRICE 25s. Carriage paid to any Railway Station.
May be had from Ironmongers, Gas Fitters, and Instrument Makers, &c.
The BRITISH INSULITE CO., Limited,
20, COLEMAN STREET, LONDON, E.C.

SLIP

CAPE COLONY.—News from South Africa says that the telegraph line was opened to Tarkastad on April 7.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended May 4 were £3,039.

H.M.S. "HIMALAYA."—The Swan Company have heard by telegraph that their installation upon H.M.S. "Himalaya" worked without any hitch during her outward voyage.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of April, 1883, amounted to £45,148, and to £42,667 in the corresponding period of 1882.

THE TELEPHONE IN NOTTINGHAM.—We are informed that the messages passing through the National Telephone Company's Exchange at Nottingham now exceed 1,000 per day.

BURNING OF A DYNAMO SHED.—An American paper says:—"The building containing the generating apparatus of the Brush Company, at Cincinnati, was burned on the 21st instant."

THE PATENTS BILL.—Owing to representations which have been made to the Government, it is understood that an earnest endeavour will be made to deal with the Patents Bill during the present Session.

THE UNITED TELEPHONE COMPANY.—Between the 1st of January and the 1st of May this year the United Telephone Company have added 390 new names to the list of subscribers to their metropolitan exchange.

MR. FAWCETT.—*The Times* Paris correspondent says that Mr. Fawcett is likely, on Saturday (to-day), to succeed the late Mr. Newmarch as Corresponding Member of the Academy of Moral and Political Sciences.

THE LUMLEY COURT AT THE AQUARIUM.—On the occasion of the National Liberal Club banquet, held at the Westminster Aquarium the other day, Mr. Gladstone utilised the Lumley Court as his reception room.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of April, 1883, amounted to £32,005, and to £29,269 for the corresponding period of 1882, being an increase of £2,736.

ROYAL SOCIETY.—At this society's meeting on Thursday last, Professor Hughes was to read a paper on a "Theory of Magnetism based upon New Experimental Researches," in continuation of a previous paper on the same subject.

DEVON AND CORNWALL ELECTRIC LIGHT COMPANY.—Mr. Justice Chitty has fixed the 18th of May, at his chambers, in the Royal Courts of Justice, Strand, as the time and place for the appointment of an official liquidator for this company.

CORK INDUSTRIAL EXHIBITION.—The tender of Messrs. Emerson, Murgatroyd, and Co. for lighting the Cork Exhibition building with incandescent lamps has been accepted. The Earl of Bandon has consented to open the exhibition on the 3rd July.

IRISH CABLES.—The *Daily Telegraph* of last Wednesday says:—"It is stated that one of the telegraph cables between England and Ireland is to be immediately taken up for repairs, and that a great delay in the transmission of messages is consequently anticipated."

THE METEOROLOGICAL SOCIETY.—At the ordinary meeting of this society, to be held on the 16th inst., at seven p.m., the following paper, amongst others, will be read:—"New Method of Reading a Thermometer and a Hygrometer at a Distance by means of Electricity," by Arthur W. Waters, F.G.S., F.Z.S.

THE AMERICAN BRUSH COMPANY.—The works of the Cleveland Brush Electric Company, including their new addition, which is now almost completed, cover six acres of ground. A draft stack which the company have recently put up is capable of making a draft for engines and boilers aggregating 1,500 horse-power.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the Board of Directors, held on Wednesday, the accounts to the 31st December last were submitted, and showed a balance of £21,201 4s. 7d. on revenue account. The directors decided, after placing £15,000 to reserve, to carry the balance of £6,201 4s. 7d. forward.

TO BE WOUND UP.—The Anglo-General Electric Light Company, of 4 and 5, Three Crowns-square, Southwark, S.E., and the Anglo-Colonial Electric Light Company, of the same address, are to be wound up voluntarily. Mr. C. F. Reynolds, of 13 and 14, King-street, Cheapside, E.C., has been appointed liquidator in both cases.

LONDON PLATINO BRAZILIAN TELEGRAPH COMPANY.—The revenue of this company for the month of December is estimated at £2,015 (Western Brazilian portion, £1,325; Land Lines, £690), as against £2,106 for the corresponding period of 1881. The directors announce a final dividend of 3s. per share, being at the rate of $2\frac{3}{4}$ per cent. per annum.

THE JABLOCHKOFF SYSTEM.—The Strand Vestry has decided to give the lighting of its parishes, including St. Anne, Soho; St. Paul's, Covent Garden; St. Clement Danes, St. Mary-le-Strand, Liberty of the Rolls, and the precincts of the Savoy, to the Jablochkoff Electric Light and Power Company, under a seven years' license. This company have erected several of their lamps outside the Gaiety Restaurant, in the Strand.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company in April, 1883, amounted to £20,490. For the period 1st January to 30th April, 1883, they were £76,920, against £72,350 for the corresponding months of 1882, and £71,156 for the same period of 1881. A final dividend of 6s. per share for 1882 is now payable at this company's bankers, Messrs. C. J. Hambro and Son, 70, Old Broad-street, E.C.

THE ZANZIBAR-MOZAMBIQUE CABLE.—An Exchange Telegraph Company's telegram, dated 4:20 p.m., Thursday, says: "The Eastern Telegraph Company announce that the repairing ship 'Great Northern' has now buoyed both ends of the Zanzibar-Mozambique cable, and is seeking for a better bottom in which to relay the cable, which has broken three times in the same locality. The communication is expected to be shortly restored."

LICENSES FOR TELEPHONE LINES.—The chairman of the National Telephone Company writes to a daily paper as follows:—"I have had negotiations with the department in reference to inter-town telephonic communication, and the Postmaster-General has refused to my and to all other private telephone companies the license to erect trunk wires between town and town. He, however, undertakes to do the work himself, and to let the wires to the telephone companies."

TELEGRAPH MATERIALS WANTED.—The Great Eastern Railway Company are inviting tenders for the supply of telegraph materials, india rubber, &c. Forms of tender can be had on application to the secretary's office, Liverpool-street Terminus, E.C. The patterns may be seen at the Stores,

Digitized by Google

Stratford, E., between 10 a.m. and 4 p.m., from 16th to 24th inst. inclusive. Persons applying should state the particular contract or contracts for which they propose to tender. Tenders, endorsed "Tender for Stores," must be forwarded to Mr. J. Hadfield, secretary, Liverpool-street Terminus, E.C., by 10 a.m., on the 26th inst.

Electrical Transmission of Power.—We had hoped to have been able to give a *résumé* of a report on some further experiments made with M. Marcel Deprez's machines and installation at the Northern Railway's workshops, Paris, in our present issue. The length of our correspondence and the pressure of other matter for which a place must be found in the last number of this volume has obliged us to defer the publication of this *résumé* until our next issue. We may mention, however, that the further experiments were made by a special committee appointed by the Academy of Sciences, and were carried out on the 4th of March.

Electric Exhibition at Vienna.—We are informed that the French are the first among the exhibitors at Vienna who have completed the plan of their exhibits. The French telegraph department will have a richly-decorated pavilion in the centre of the section devoted to their country, in which some valuable historical apparatus will be shown, as well as modern instruments. With this pavilion as the centre, the French section will occupy an area of 1,500 square metres; this, of course, does not include machines in action, which will be shown in the machine room. Close to France will be found the representatives of Russia, who will occupy from 300 to 400 square metres.

The Telephone in Malta.—The Compagnie Internationale des Téléphones have opened an exchange at 27, Strada Mercanti, Valetta, Malta. It is to be open day and night. The annual subscription is as low as £8 per annum, no matter what distance the subscriber may be from the exchange. The Ader transmitter and receiver are used. The wires are all of silicated phosphor bronze, a substance which is rapidly coming into repute for this class of work on account of its durability and conductivity. Branch offices have also been established at the Bourse, the central police station, Chamber of Advocates, Theatre Royal, railway station, and elsewhere. The management of the exchange has been placed in the hands of Chevalier Edward Rosenbusch, C.E., well known in the island as having been instrumental in introducing many useful novelties.

Electric Lighting in Dublin.—We understand that the new premises recently fitted up for the offices of the *Irish Times* in Westmoreland-street, Dublin, are to be lighted throughout on the incandescent system of electric lighting. The installation is to be erected by Messrs. Siemens, and will consist of 150 Swan lamps of 20 candle-power each, worked by an alternate current machine and an exciter. The lamps will be arranged in four circuits, so that one or more circuits may be cut off at pleasure, and each lamp will be provided with a switch for putting on or off the current as occasion may require. Safety plugs are also to be inserted where necessary. The dynamos will be driven by a 12 horse-power Crossley gas engine, and suitable counter shafting, a fly wheel being provided on the exciter for the purpose of overcoming the usual unsteadiness of this class of engine. The installation will be carried out under the superintendence of Mr. J. Angelo Fahie, Mem. S.T.E. and E., of Dublin.

Electric Lighting for Poplar.—At a recent meeting of the Poplar District Board of Works a report was received from a special committee appointed to consider the Brush Company's provisional order. The committee recommended that two areas in the district should be agreed upon for the operations of the company. The areas were (1) that portion of the district bounded on the west by the Blackwall Extension Railway, on the south by Archibald-street, south of the North London Railway Company's engine house to the angle of High-street, thence along High-street; and for the eastern boundary the River Lea, the specified thoroughfares affected being Bow-road and what was formerly High-street, Bow, between the boundaries named; (2) so much of the district not included in the other area as lies south of the Great Eastern Railway from Old Ford station eastwards. The amount to be appropriated in the first instance to be £7,500, and 5 per cent. of that amount to be deposited in accordance with the terms of the order.

The General Post Office.—In the House of Commons on Monday last, Mr. Ritchie asked the Postmaster-General whether it was proposed to enlarge the accommodation of the telegraph department of the General Post Office by adding a story to the present building; what height from the ground the new story would be; how many persons would be located in the building when completed; and what precautions against fire it was proposed to take? Mr. Fawcett said: "In reply to the hon. member, I may state that the height of the floor of the new story in the telegraph department above the pavement is 76ft. The maximum number of persons employed in the entire building is about 2,500. Of course the whole number are not employed at one time. About 300 are employed at night. The building is fireproof, and every precaution is taken against fire by having large tanks on the top of the building and hydrants on each floor. The means of exit are so good that it is considered that the whole staff at the busiest time in the day could leave the building in ten minutes." In answer to a further question from Mr. Ritchie, Mr. Fawcett stated that to the best of his belief no more than 2,000 persons were ever employed in the building at the same time.

Electric Light on Ships.—The new paddle steamer "Rio Pardo," built and engined by Messrs. Caird and Co., Greenock, for the National Brazilian Steam Navigation Company, to be employed on the coasting trade between Rio de Janeiro and Buenos Ayres, went her official trial on Thursday week (May 3), and proved in every respect a great success. The dimensions of the vessel are as follow:—Length, 272ft.; breadth, 34ft.; and depth from spar deck, 19ft. 8in. The engines are compound oscillating, of a nominal power of 300 horse, working to 1,600 horse, the cylinders being 45 and 80 by 60. Two multitubular double-ended steel boilers with eight furnaces give a full "head" of steam. The vessel has been fitted throughout with electric light by the Edison Electric Light Company, under the supervision of Mr. C. T. Grant, Glasgow, and Mr. Cochrane. The Union Steamship of New Zealand have entrusted the lighting of their new mail steamer the "Takapuna," now finishing at Barrow, to the Edison Electric Light Company. When completed this will form the third vessel of this line which has been lighted on the Edison system, two others being lighted by means of Swan lamps and Siemens dynamos. We are glad to find that the company have such faith in electric lighting.

Telegraph Clerks at Belfast.—In the House of Commons on Monday night Mr. Biggar asked the Postmaster-General if it was true that there were a number of telegraph clerks in the Belfast office, with from nine to twelve years' service, performing night and Sunday duty, who were only allowed two weeks' annual leave, while others in the same office with only six or eight years' service, performing exactly similar duties were granted an annual leave of three

Digitized by Google

weeks; if that were so, why was this distinction made between members of the same staff of the Belfast office, and would he have the anomaly removed; and if it was not also a fact that clerks in the Dublin office, with similar service, and performing precisely the same duties, were allowed three weeks' leave in the year. To which Mr. Fawcett answered:—"I stated, in reply to a question put to me last year, that the telegraph clerks at Belfast had been found to be enjoying exceptional indulgence in the matter of annual leave of absence, and this indulgence, while continued to those who already enjoyed it, was not to be extended to others. The officers referred to as having only a fortnight in the course of the year, though of longer service than some who have three weeks, have entered the Belfast office since the difference between that office and others has been discovered. As regards Dublin, I may state that some time since it was decided that future entrants into that office would be allowed only the same period of annual leave as the staff at Belfast."

M. Philippart.—A telegram from Paris, dated Monday night, says:—"The financier Philippart, who has been for several days in the Conciergerie, was this morning sent in custody to Brussels, the French Government having come to the conclusion that a good case for his extradition is established." M. Philippart has also written to the daily papers, enclosing a copy of a letter which he has addressed to the Minister of Justice in Paris. The letter is to the following effect:—"Paris, May 5.—M. le Ministre,—When the Belgian Parquet first asked for my extradition upon an accusation that I had falsified and destroyed the books of the 'Société la Force et la Lumière,' I considered it my duty to resist, for the demand was illegal in form and unjust in principle, the books in question having been placed in the hands of the Belgian Parquet from the commencement of the proceedings. The statement drawn up by my counsel, Maître Clunet, and approved by Maître Senart, proves this conclusively. Evidently my course of action was only too correct, for to-day the Belgian Parquet, in answer to my defence, sees fit to to formulate a charge of forgery against me. This charge is most odious, and will not bear examination for a single instant; but my honour requires that I should be in a position to defend myself, and therefore it is now I who request the French Government to accord my extradition, and with the least possible delay, in order that I may confound my accusers before the Belgian Tribunals.—I beg you to accept, M. le Ministre, the assurance of my highest consideration, (Signed) Simon Philippart."

British Association.—The fifty-third annual meeting of this association is to be held at Southport in September next. The President elect is Professor Arthur Cayley, F.R.S., of Cambridge University. The following is the official programme of the general and evening meetings:—The first general meeting will be held on Wednesday, September 19, at eight p.m., when Sir C. W. Siemens, D.C.L., F.R.S., will resign the chair, and Professor Cayley, F.R.S., President elect, will assume the presidency, and deliver an address. On Thursday evening, September 20, at eight p.m., a *soirée*; on Friday evening, September 21, at 8:30 p.m., a discourse on Recent "Researches on the Distance of the Sun," by Professor R. S. Ball, LL.D., F.R.S., Astronomer Royal for Ireland; on Monday evening, September 24, at 8:30 p.m., a discourse on "Galvani and Animal Electricity," by Professor J. G. McKendrick, M.D., LL.D., F.R.S.E., Professor of Physiology in the University of Glasgow; on Tuesday evening, September 25, at eight p.m., a *soirée*; on Wednesday, September 26, the concluding general meeting will be held at 2:30 p.m. The officers of Section A, Mathematical and Physical Science, are as follow:—President: Professor Henrici, Ph.D., F.R.S. Vice-Presidents: Professor Balfour Stewart, F.R.S., and Professor Stokes, D.C.L. Secretaries: W. M. Hicks, Professor O. J. Lodge, D.Sc.; D. McAlister, D.Sc. (Recorder); Professor Rowe, B.Sc. Those of Section B., Chemical Science, being:—President: J. H. Gladstone, F.R.S. Vice-Presidents: Hugo Müller, F.R.S., and Professor T. E. Thorpe, F.R.S. Secretaries: Professor P. Phillips Bedson, D.Sc., F.C.S. (Recorder); H. B. Dixon, F.C.S.; H. Foster Morley, B.Sc., F.C.S.

Manchester Electric and Gas Exhibition.—The exhibitors held a *conversazione* on Friday last in connection with the Manchester Electric Lighting, Gas Lighting, and Engineering Exhibition, and there was a large attendance of ladies and gentlemen who had been specially invited by the committee. An excellent programme of music and other entertainments was provided, with several novelties on the application of electricity, including the electrical tricycle. Mr. W. E. Heys also delivered a short lecture on electric lighting, popularly explained and illustrated by experiments. The point chiefly dealt with by Mr. Heys was the progress made in the development of accumulators or storage batteries, the construction and principle of which he explained. Without attempting to indicate all the uses to which these storage batteries might be applied for the development of motive power, there was one convenience attending their use to which he said he might specially allude. This was in the fact that, whereas with a dynamo alone they had an unalterable pressure or electromotive force, with the storage battery they could, by division or addition, obtain any pressure that might be desired, and the resulting current would in all cases be absolutely steady and free from those pulsations which they might observe in lamps deriving current direct from a dynamo, especially where the dynamo was driven by an unbalanced gas engine. He also wished to remove what he found was a popular impression, that the accumulators had to be removed from the place of their use to a central station or elsewhere for charging. This, save in exceptional cases, was not the case; the storage batteries were just as much a a part of the permanent installation as the dynamo itself, as they might be charged or discharged through any reasonable length of conductor.

Chelsea Vestry and Electric Lighting.—At the last meeting of the Chelsea Vestry a report was received from the Electric Lighting Committee to the effect.—1. That they have received from the Board of Trade printed circular letters, dated April 13, and orders therewith, in respect of the Chelsea electric lighting, the South Kensington district electric lighting, and the Victoria district electric lighting, from which it appears that the Board of Trade have so far modified their views that whereas they formerly suggested that the amount of capital to be deposited or secured should be one half the amount required to execute the works, they now require that such amount should "not exceed" one half. The committee consider that it will be gratifying to the vestry to learn that the Chelsea electric lighting order, being the first completed one, has been adopted by the Board of Trade as the basis for orders generally, and has been sent by that Board to such local authorities and electric lighting companies as are concerned in similar applications. 2. Submitting that they have received from their chairman a report from which they learn that the Metropolitan Brush Electric Light and Power Company have proposed to reduce the number of streets in Schedule A to be compulsorily lighted within the two years, by omitting Hans-place and the portion of Pont-street west of Sloane-street, and by so doing to diminish the amount of

Digitized by Google

capital to be set aside from £30,000 to £20,000; and have further proposed that the sum to be deposited or secured shall not exceed £10 per cent. thereon, and reporting that in consequence of the Board of Trade requiring a reply before the 23rd instant, they have, on behalf of the vestry, agreed to such proposals, and have notified the Board of Trade accordingly. On the motion of Mr. Mossop (chairman of the committee) the report was unanimously adopted, and he and the surveyor (Mr. G. H. Stayton, C.E.), were authorised to settle the remaining details of the order.

Australasian Electric Light Company.—A circular has been sent to the shareholders in this company giving some account of Sir Julius Vogel's visit to Australia and New Zealand on behalf of the company. We make the following extracts:—"It is evident now, from Sir Julius Vogel's reports, that considerable time was lost to the company from several causes, foremost among them being the fact that the predilection of the public in the colonies was, in the first instance, more in favour of incandescent than arc lighting, while the plant at the command of the company was at first exclusively arc plant. An important sale, however, of the latter has been made to the Victorian Government, together with a couple of incandescent machines, consequent upon the great success of the lighting of the Spencer-street Railway Station in Melbourne, the terminus of the greater part of the extensive railway lines of that colony. In Sydney, too, the Government are in the same way likely to take over an extensive installation at the Circular Quay, and in New Zealand the local company has secured the Lyttelton Harbour against all competitors. Other sales of arc plant have taken place, but the chief demand for internal lighting is undoubtedly for the incandescent system. In this Sir Julius Vogel reports there is practically an unlimited field, and there can be now absolutely no doubt as to electricity being the cheaper and better illuminant for these climates. It is also the directors' view that a very large field is opening for profitable business in the colonies, the cost of the incandescent light being estimated, on sound authority, at very much less than that of gas in any of the colonies, and the great heat of the climate giving a further immense advantage to electricity. A fair amount of incandescent plant has now reached the company's agents, after many disappointments on the part of manufacturers. Victoria and New South Wales have been reserved for the development of business by the company itself, while in New Zealand, South Australia, Tasmania, and Queensland, the formation of local companies is being carried out with, it is believed, every prospect of success."

Underground Wires in New York.—From the *New York World* we learn that a meeting of the General Committee on Underground Electrical Communication was held on Wednesday, April 25th, in that city. The committee consists of Governor Cleveland, Mayor Edson, and the following gentlemen:—H. L. Bailey, Time Telegraph Company; D. H. Bates, Western Union Telegraph Company; A. B. Chandler, Fuller Electrical Company; W. A. Childs, Law Telegraph Company; H. Cummins, Postal Telegraph Company; L. E. Curtis, United States Electric Light Company; J. P. Davis, Metropolitan Telephone and Telegraph Company; S. S. Eaton, Edison Electric Light Company; C. R. Flint, Western Electric Light Company; R. R. Hazard, Gramme Electrical Company; E. Holmes, Holmes's Burglar Alarm Telegraph Company; C. D. Hotchkiss, Mutual District Messenger Company; W. M. Ivins, Jablochkoff Electric Lighting Company; F. R. May, American Rapid Telegraph Company; T. J. Montgomery, Brush Electric Company; G. S. Mott, Bankers and Merchants Telegraph Company; H. W. Pope, Manhattan District Telegraph Company; C. W. Price, Baltimore and Ohio Telegraph Company; A. C. Richards, Automatic Signal Telegraph Company; J. Eliot Smith, Fire Department Telegraph; Elihu Thomson, American Electric Company. Representatives of the Gold and Stock Telegraph Company, the Mutual Union Telegraph Company, and the American District Telegraph have yet to be appointed. Mr. J. P. Davis was elected chairman, R. W. Blackwell treasurer, and H. C. Behrens secretary. Mr. Robert B. Minturn, in a short speech, said that he was confident that the present Bill compelling companies to place their wires underground would not pass the Legislature. It ought not to pass, because it was tyrannical and unjust. The companies were not unwilling, but unable, to accede to the popular demand, and they were ready to adopt any feasible system. Mr. William M. Ivins said that concerted, harmonious action ought to be taken at once to devise some practical solution of the problem. There were great difficulties in the way, and they should be carefully considered before any steps were taken. Remarks were also made by other gentlemen.

Perry v. International Ocean Telegraph Company.—Judgment in this case was delivered on Monday last by Lords Justices Baggallay, Lindley, and Fry. The suit was instituted in 1874, and the hearing before Vice-Chancellor Bacon occupied nearly a fortnight in June, 1881. The bill was filed by Mr. Horatio Justus Perry, an American citizen, against the International Ocean Telegraph Company (an incorporated American company of the State of New York), the West India and Panama Telegraph Company, and the India Rubber, Gutta Percha, and Telegraph Works Company, the case being as follows: In 1866 the plaintiff entered into agreements with the International Company, and the defendant, Charles Knap, under which he was to endeavour to obtain a concession from the Spanish Government for establishing a system of telegraphic communication between Spain and the Spanish West India Islands, Cuba, and Porto Rico. On obtaining such concession he was to assign a portion of the privileges conferred by it to the company, and the remainder to Mr. Knap, receiving in consideration a fixed sum from the company, and from Mr. Knap a moiety of the profits which he should derive from the sale of the portion of the concession assigned to him, it being then contemplated that the sale should be made to a company. The concession was obtained and assigned as agreed; the company paid the consideration agreed to be paid by them, but that which was to be given by Knap was not made good to the plaintiff, who alleged that it was now represented by £25,000 worth of shares in the West India and Panama Telegraph Company, and he prayed a declaration that he was entitled to those shares, and other relief. Under the concession from the Spanish Government the West India Company (a company promoted by the International Company) had the exclusive right of telegraphic communication between Cuba, Porto Rico, Panama, the Windward Islands, and Demerara. The plaintiff contended that Knap had been a trustee for the International Company, or at all events its agent; and that under the agreements of 1866 he had a charge on the concession and the fruits of it. The first contention having been abandoned at the bar, it was argued that by subsequent agreements the International Company had taken the place of Knap. It was further contended that there had been a wrongful sale to the West India Company, and that the plaintiff might waive the tort and take the fruits. Vice-Chancellor Bacon dismissed the bill, with costs, and the plaintiff appealed. Their lordships dismissed the appeal, with costs.

A GUIDE TO PRACTICE IN THE SUBMARINE CABLE TESTING ROOM.

No. XXIII.

The staff arrangements in connection with the submergence of a cable depend on various conditions, such as the length to be laid, the situation of the line, the number of stations between which sections are to be laid, the order of laying, and other matters. A cable recently laid in South America required a very large staff, as there were so many stations, and there were, therefore, a great many shore ends and separate testing places. A long cable, such as an Atlantic line, would have two or at most three or four shore stations, and at two of these the staff would consist of four electricians at most, one of whom is chief, and should have good experience of the work. It is very desirable that all should know the mirror signals; there is sometimes a mass of correspondence between the ship and shore, and every minute is valuable. A staff of three assistant electricians is necessary on board besides the chief electrician who always accompanies the ship. The shore ends are laid on the first favourable opportunity after the ship arrives on the spot, and if, as often is the case, this operation is performed at some date earlier than the time fixed for the main length to be laid, the sea end is buoyed, and the other end, of course, brought into the testing room on shore, generally a wooden hut erected for the purpose. The instruments should be in position as soon as possible, and if they are landed at the same time as the shore end the electrician will get them arranged as quickly as may be, there being time for sufficient adjustment for a fair test whilst it is being laid, and the details can then be finally fixed more at leisure. But if the main length is to be laid as soon as the shore end is landed, the testing arrangements will have been previously made, that no delay may occur.

The proceedings on board and on shore are precisely the same for all long cables, though in some details a little variation may be seen in the instructions given by different chief electricians. The main object in all cases is to maintain a constant intercourse between ship and shore, and a continually recurring set of signals at short intervals to show that all is correct and the cable insulation always good. As regards those for whom we are more immediately writing, our suggestions will be divided into two parts, one relating to the work on board, and the other to shore station duty. These are very much the same, though not entirely so. The ship is the head-quarters, and all the instructions originate there—shore must rigidly obey ship.

The arrangements for maintaining communication between ship and shore cannot be better set forth than in the exact words of a sheet of instructions drawn up by the chief electrician for the laying of a long cable recently from Europe to the West. We venture to reproduce a portion of these sufficient for our immediate purpose, as they are remarkably clear and concise.

"The principal tests are taken on board ship, where the cable is connected for insulation test by deflection on ship's galvanometer. The deflections are recorded every minute and the first . . . (and certain other) minutes worked out in the ordinary way and recorded. The negative current will be put on at the exact hour and reversed every fifteen minutes.

"On shore the cable is connected to one side of a condenser, the other side of this condenser being connected through a speaking galvanometer (mirror) and signalling key to earth. Thus this galvanometer is always ready for receiving from ship. . . . The cable is also connected to the working contact of a single lever key, the other terminal being connected to earth through an astatic galvanometer, and the bar terminal to a condenser, the other side of which is to earth. At every five minutes, commencing at the second minute after the hour, the key is depressed for ten seconds, thus charging the condenser from the cable, causing a throw on ship's galvanometer, and serving for a continuity signal to ship; the key will then be released and the deflection on the astatic galvanometer recorded—the direction, left or right, depending on the current from the ship. . . ."

A plan accompanying these instructions would vary a little from the figure now given (Fig. 47), but in all respects the principle is the same. The shore station connections shown in this figure are rather squeezed to economise space, and the following points must be noted:—The galvanometer on the right (facing us) is connected to the four-way piece, and would be joined direct to earth by a wire from the vacant terminal; but sometimes this requirement is effected by the lead from the testing key T K which is seen with its end loose; the earth is then made through the upper bar and by the earth wire on the other terminal. The four arrow-heads placed together represent the means for introducing into the circuit the large condensers S C for speaking. They are at certain times disconnected, and we have, therefore, merely indicated their position. We will just go over the figure, referring where necessary to the instructions given above, there being some slight difference.

The round commutator marked D has five contact points, the cable being joined to the centre. Each of the four other connects to the centre point by a series, which, when put down, presses on a spring, and thus effects communication with it. When not screwed down there is no connection with the centre. One terminal has an earth wire, one has a lead for joining up to a Wheatstone bridge when required, one connects with the switch V, and the fourth is joined up to the Lambert key, which in

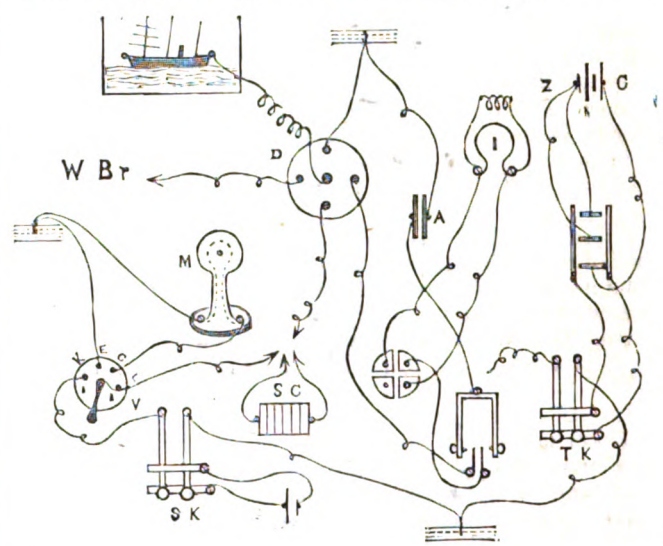

Fig. 47.—Connections at Shore Station, long Cable laying.

this figure replaces the contact key mentioned in the instructions. The condensers S C represent the condenser spoken of in that quotation as having the cable connected to it. Taking the plan from the right hand, we have the testing battery at the top, with the battery commutator below, and under it is the testing key T K, then the discharge key, the galvanometer and its commutator. On the left is the speaking key S K, the switch V, and mirror M, with the condensers ready for inserting. The small condenser A is the second one referred to in the instructions, and is of the same form as illustrated in a recent number, enabling us to use any amount from 1 up to 20 microfarads. The cable is supposed to be paying out from the ship in the far distance—any number of miles off. Turning now to the duties at the shore station, we will suppose that the shore end has been landed, and that a length of perhaps 100 knots has further been submerged on a separate expedition preceding that now before us. The sea end will be on board and the other end is all ready in the shore testing room, with all connections prepared for the main expedition. The chief electrician in the ship will give instructions as to the time when they expect to arrive at the spot where the cable is buoyed, and the electricians at the shore station must be on the alert for the important occasion. The shore end will have been landed in sufficient length to admit of a good quantity of spare cable. The portion emerging immediately from the sea

Digitized by Google

is laid in a trench dug for it, and several large coils are then buried near the hut, leaving a length of a few fathoms to the end, which is then brought into the hut, and a few yards stripped of its sheathing and hemp covering, leaving the core exposed, and the end brought up to the table. A few inches of the gutta percha are stripped off, leaving the conductor so far bare. When joined up for the expected arrival of the ship at the buoy, the end is connected directly to the speaking mirror M, so that the slightest signal is at once received. In the figure the end is not so connected, the plan being intended to show the arrangement after the regular laying is begun. The ship will be brought to the buoyed end as nearly at daylight as can be managed; if the buoy is no further distant than a hundred miles west of the shore station the time will be nearly the same at both places. An assistant will therefore start watch at two or three hours before the time ordered by the ship, when the connections must be carefully looked over, and everything right. The spot of light from the mirror falls on a piece of white paper on a little stand, movable as required. The electrician on watch must keep his eye on this, and wait for the signal from the ship. The spot may not be perfectly steady at this time, hough in a length of 100 knots there may not be much disturbance from earth currents, but there need be no difficulty in this respect. The cable being joined to the mirror coil, and no battery being in acting circuit, the first sure sign of the ship having got the end will be given by the electrician on board sending a current through the line.

The spot will fly off the scale, and dart back and forward, the signals being small or large according to the number of cells used. Five or seven will probably be the number, but the first sign is always the same, being the call signal . . . — . The moment the assistant sees the movement he must disconnect the cable end from the mirror, and join it to K on the switch, at the same time joining the point G to the terminal from which he has removed the cable. He has now the means of answering as well as receiving signals. The leads will be in their places ready for these or other changes. He will now use his speaking key, S K, and answer the call by repeating the same sign. Ship will probably reply "decrease battery power," or the contrary as may be. We must therefore alter our battery by changing the negative lead from, say, the 7th cell to the 4th and then call ship, also ask him to increase or decrease in his turn if the signals are too small or too large. Ship then sends some messages and gives some orders, and then, when the cable has been spliced, orders regular testing to begin. The connections are now arranged as in the Figure 47. At the exact time to a second, as mentioned in the instructions above, the electrician on duty depresses the left-hand side of his discharge key for a moment, and then, releasing it, touches down the other side, carefully reading the deflection from the galvanometer, and entering it in the book before him. When ship reverses his current he will observe it, and particularly see if the time corresponds to a second with his own clock. This is seldom exactly the case; therefore, if, for example, he finds ship time one second faster than his he must count his five minutes from one second earlier than before, always keeping ship's time.

As long as all is well these continuity signals go on, with occasional interruptions for messages, some of which are periodical, giving ship's position, depth, length paid out, &c., but in cipher, as nearly all are, until it is necessary to splice on another length of cable on board. Ship gives warning of this, and advises the time when his current will be taken off. When that time has arrived, the spot disappears (and returns), and after some short interval, during which the cable is disconnected on board and the conductor is being jointed to that of the fresh length and the gutta percha laid over, ship calls again. The joint is so far completed as to allow of communication, and signals are interchanged whilst the splicing is being finished, a period of about half an hour. Ship also advises what changes are to be made, for instance, in the amount of condenser to be now used, &c., and, when ready, orders regular testing to recommence. Our space being so limited, we cannot prolong this account of the regular work. All goes on in the same way, unless an accident happens or a fault occurs. Sometimes the cable breaks suddenly, even in the middle of a message; observing the sudden stoppage of signals, shore must call for a certain time, and if he gets no answer must alternately put to earth and insulate the cable for, say, ten minutes each time (in case of ship being able to test), and join at times to the speaking mirror. He does this for some hours, when, having no signals, he will either connect the cable direct to the mirror as at first, or to a relay, so as to ring an electric bell if a current is sent through it, and also takes tests every hour. Days and weeks sometimes pass without communication, and watch must be constantly and ceaselessly maintained. It is safer to join direct to the mirror than to a bell, as earth currents often cause false alarms by ringing it. During the absence of communication it is well to observe these earth currents, watching their course, rise and fall, &c., and recording the facts. The hours of duty are divided as fairly as possible, but every one must be prepared for any length of watch, and in some positions accommodation is of the roughest. Cable huts are always in out of the way places, and necessarily so. Attention to "little things," as some persons sneeringly call them, is very important, such as making sure that the lamps are regularly filled and attended to. The spot of light is the tell-tale, and must be constantly maintained. Earth currents at certain times prevail in one direction for hours, then return, and act in the opposite

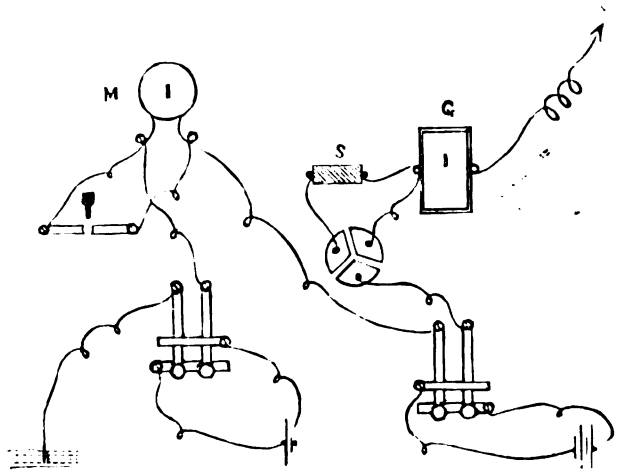

FIG. 43.—Connections on board during submergence.

direction. The spot is during these times pushed (so to speak) further and further, until it passes far off the little scale, indeed becomes invisible from the interception of the rays by the face of the mirror itself, as the actual mirror and little magnet are hung at the end of a hollow way, and the range of play for the light is small. Any way the spot disappears, and even the directing magnets of the mirror will not bring it back. It is necessary then to place a strong horseshoe magnet alongside the mirror stand, turning its poles in the proper direction to act on the little magnet inside, and so turn it back. The earth currents are at times very strong indeed, equal to many cells. If the assistant on duty observes irregularity in the signals he must look over his connections, and, if all is right, must advise ship, as perhaps there is a fault. The strong sign of this would be the continuity signals becoming smaller.

A word or two on the duties of the assistant on board. He has to watch and record the deflections every minute, as pointed out in the instructions. A constant is previously taken, by which the results are worked at stated intervals. The rolling of the ship and other causes produce a wandering, disturbed motion of the spot, very different from the steady deflection in this (insulation) test on shore. The number of divisions must be estimated as nearly as possible. The length being uniform, the deflections do not vary very much, but it is at times impossible to be sure of the figures. If any great irregularity of the signals appears, the electrician on duty

Digitized by Google

must give the alarm (by sounding a gong is the best way), when the ship will be stopped, and a fault will be looked for and tests taken, or, if the cable is broken, the ship will grapple till it is picked up. The connections on board may be represented by Fig. 48. They explain themselves. We have added one more figure (Fig. 49), giving a plan of connections at a station for a shorter cable; where no good earth is available, the sheathing of the cable is made to do that duty.

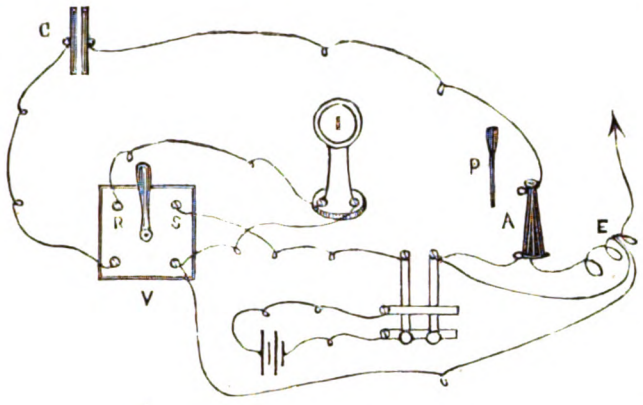

FIG. 49.—Connections on shore, earth on Cable.

Our series is unavoidably closed for the present. There are many important branches which remain for consideration, and we have been compelled to abridge our explanations, in some instances considerably. The subject, as far as it has reached, is appropriate to the requirements of one who has experience still to acquire.

F. S. BEECHEY.

ELECTRIC LIGHTING OF CANTERBURY.

Report of Mr. T. H. BLAKESLEY, Assoc. M.I.C.E., upon the (Draft) Provisional Order applied for by the South-Eastern Brush Electric Light and Power Company.

We have so often recommended municipal authorities to obtain the advice of competent men upon the schemes for lighting proposed for the districts under their supervision, and we think the opinions expressed in the reports of such competent men so important, that we do not hesitate to devote a considerable amount of attention to these matters. The report of Mr. Blakesley is fairly exhaustive, and his remarks should be read with the draft provisional order applied for. The latter is, according to law, published at a nominal price, but, of course, the report is a private matter between the authority and its adviser. We have to thank the Town Clerk of Canterbury and Mr. Blakesley for putting the report at our service.

Mr. Blakesley holds very strongly to the opinion that in no case should electricity be so supplied as to be applicable for one purpose only, and we entirely agree with this view. Gas as supplied may be used for lighting or heating purposes, or for use in a gas engine, &c. Mr. Blakesley says:—

"The granting of any monopoly for the supply of electricity would be, under any circumstances, only excusable if the electricity is supplied at a reasonable cost for all reasonable purposes to which it is applicable. It would be most unfair that any inhabitant should be debarred from obtaining for a reasonable price electricity suitable for mechanical application simply because the undertakers elect to supply electricity in a form under which it cannot be so employed, viz., in an alternating current. It would, again, be unfair to oblige a customer to employ a form of lamp of a more wasteful and uneconomical description than another only because the undertakers do not choose to maintain a proper and not unreasonable pressure in their mains. Now, although there is no monopoly directly sought, yet it seems to me probable that when the Brush Company shall have obtained the lighting of the City of Canterbury (presumably the most certainly remunerative part of the business of the district), no other company is likely to come into the city with an offer to supply electricity for other purposes than lighting. It is not likely that the attempt to do so would be commercially successful. At all events, if the Brush Company contends that there is a fair chance of such an attempt being commercially successful, there will be the less reason why the Brush Company should not be bound to supply electricity (at fair prices) for all purposes for which electricity may be required by the inhabitants of the city. If it should turn out that electricity is not wanted, except for lighting, there will be no injury inflicted on the Brush Company by inserting in the order proper provisions for compelling it to supply the want when it arises, but in the contrary event I submit that it will be very unfair to the public of Canterbury that the supply of electricity for other than lighting purposes should be dependent upon the will of the company, which will have established a practical monopoly for twenty-one years. The company should be prepared for all reasonable demands. . . . To meet this end, too, the company should be compelled to employ continuous currents, and for other reasons it is desirable to prevent the use, except under special agreement and under special conditions of insulation, of alternating currents. The alternating current can be used for little else than for lighting, and for this purpose a non-alternating current is as serviceable. Moreover, the alternating currents are dangerous, and the amount of energy supplied by them is not readily indicated by meter. The words 'alternating current' mean one in which the direction of the current is changed many hundred times, and even many thousand times, in a minute. Not only should the current be non-alternating in this sense, but the undertakers should be bound to keep the positive main at one time always positive and the negative main always negative. This is necessary for the due action of many lamps, of many dynamo machines, and of all storage batteries which may be used by consumers in connection with their supply."

It would have been better, perhaps, if the condemnation of "alternate currents" had been less sweeping. Those who have given great attention to the subject will not admit the impossibility of using alternate currents to transmit power, and it seems they are probably right, but the question as to the economy of the transmission of power by alternate currents in comparison with that by means of continuous currents has not yet been solved. Another important question is, if the electric light is to be introduced into a town, is it right that the undertakers should say thus far will we go and no further—the gas company may go further, but we choose the best paying part of the city, and do not mean to take bad and good together? The report on this head says:—

"I quite concur in the opinion which the Town Council have already formed, that there should exist some power to compel an extension of the streets mentioned in Schedule B, and I do this on the grounds I have given for demanding other alterations, viz., that there will be a practical, if not a nominal, monopoly established. I would go even further than the Town Council propose by amending Section 18 so as to include all streets in each district, or at least all in which gas has been consumed. By this means, after the Board of Trade has once issued a requisition for any particular district, the onus of praying for any modification would rest with the company and not with the Corporation. In principle I hold that it is right that the company should on reasonable terms be bound to supply their whole district. For it is only natural to expect that the profits of the gas company will show a diminution, at least during the time that the Brush Company's prices are put at a rate to bid for custom. And if the profits of the gas company are diminished, that company may take advantage of the sliding scale to raise the rates for gas, and thus the inhabitants of streets in which the undertakers may decline to supply electricity, although lying within their area of supply, may materially suffer. Having regard to the discretion which Section 18 leaves to the Board of Trade, I think that the whole of the streets in each section of supply ought to be included, or, if this would tax the powers of the company to too high a degree, then the districts should be reduced in area. It is more advantageous for the public that the powers of the company should be expended in providing electricity for all purposes and to all inhabitants in a restricted district rather than in purveying it for special purposes and to a limited extent over a wider area."

The author seems to think that in time the "series" system, or a modification of it, will be introduced into house-lighting, and suggests fuller details if this plan is to be adopted. Although the series system seems to lend itself to economy, we doubt not that its disadvantages are too great to lend itself to household lighting. The minimum E.M.F. in the mains, 30 volts, is regarded as absurd; but we are not sure that even this low E.M.F. might not be found useful, not for 16 candle-power or

Digitized by Google

20 candle-power lamps, but for 2 or 5 candle-power lamps to be used in bed rooms, nurseries, &c. The author is of opinion—

"That a consumer should have a pressure of 100 volts at his poles, which would enable him to employ the economical Edison lamp of 32 candles, should he desire to do so.

"I think it desirable, therefore, taking into consideration the reductions the powers of the undertakers enable them to make, the minimum pressure at the mains should be one hundred and fifteen instead of thirty. I have to point out another matter in this section. If the standard pressure is to have a different value at different hours, a wrong will be liable to be done to the consumer should the undertakers elect to charge him by any but the first method of Schedule 6, in which case no obligation is put upon the undertakers to consider the varying character of the standard pressure in estimating the energy to be charged to the consumer. Section 22 (*b*) should be further amended as follows, viz., by omitting all after the word 'mains' in line 16, page 9, and substituting the following:—'But unless the undertakers charge the consumers by meters registering directly the energy supplied, the standard pressure for any pair of corresponding points of the said mains shall not vary at different hours during the period of supply,' or words to the same effect."

The figures quoted in the report are those given in Crookes's report on the lamps at the Paris Exhibition, and it is but just to point out that considerable adverse criticism has been offered to this report. It has been said that, *e.g.*, the Swan lamp is normally of 20 candle-power, the Edison 16 candle-power, and, therefore, any comparison of Swan at 16 candle-power with Edison at 16 candle-power, is necessarily against the former, and so on in other cases. In discussing the charge for electricity the author says:—

"The energy of electricity, which is the valuable commodity for which the company is going to ask you to pay, differs from gas in the following important particular:—Presuming that the gas pipe is perfect and that there is no outlet for a certain length, we know that whatever gas passes into that section at the one end passes out again at the other. But in the case of electricity the passage along any conductor necessarily absorbs the energy of the electricity to an amount depending upon the nature of the conductor and its size, but very well understood. The greater the resistance the greater the loss. Thus the house services and the meters and fuses and other apparatus through which the current may pass, all absorb energy for which the consumer must pay. Now Section 21, Clause (*d*), allows the undertakers to put down service lines (under which term is not included any meters, fuses, or other apparatus), which, in effect, will absorb 5 per cent. of the energy which is used between the junctions of the house lines with the distributing mains. Thus on this account alone 5 per cent. of energy is generated by the undertakers merely to sell it. This may be taken as all waste, for if the house line were constructed properly the resistance would be inappreciable. It will be quite necessary, therefore, to include the meters, fuses, &c., in the meaning of the words 'service lines," for the purposes of this clause. Further, as some meters have an effect in reduction of the pressure at the poles, which is not only of the nature of resistance, it will require to be taken into particular consideration."

Alterations in the order are suggested. Why should the consumer pay for this loss if it is to amount to 5 per cent.? But, again, why should it amount to 5 or ·005 per cent.? If loss there must be, then in the long run the consumer will have to pay; but we should prefer the payment for loss to be indirect, just as is the payment for gas leakage.

"But, further, Clause (*c*) of Section 21 enables the undertakers to diminish the pressure at the mains 10 per cent. from the standard pressure without taking it into account in the estimate of energy to be paid for, which will be reckoned as if the pressure was kept up to the standard pressure. Now, the energy expended between the junctions of the mains is the product of three things. The first is the pressure at the mains, the second is the current which, when the resistance remains the same (and the consumer, by Section 63 (*f*), is forbidden to reduce it on the pressure falling below the standard), is proportional to the first factor, viz., the pressure. The third factor is merely the time during which the flow goes on. It will be clear, therefore, that if the pressure becomes $\frac{90}{100}$ of the standard, the current becomes $\frac{90}{100}$ of what it would be under standard pressure, and the resulting energy is on this account $\frac{90}{100} \times \frac{90}{100} = \frac{81}{100}$ of what it would be if the standard pressure is maintained.

The effect of the Clauses (*c*) and (*d*), taken together, will therefore be different according to the method of estimating the energy adopted by the undertakers.

In the table below I have arranged the three quantities viz.: 1st. The energy consumed between the consumer's poles taken as one hundred; 2ndly, the energy consumed on his house lines and between his poles; and lastly, the energy he is charged for. If the undertakers are allowed to absorb the 5 per cent., besides an unknown quantity in meters and fuses, the case is so much the worse. It will be observed that if the first method is chosen, *i.e.*, if the actual energy is measured, the case is least unfavourable to the consumer. There is one objection to its being adopted, viz., there is no energy meter. The second case is distinctly worse for the consumer. Under this method the quantity of electricity may be measured, and when multiplied into what the pressure ought to have been, *i.e.*, the standard pressure, the product reduced to the proper number of units will be the energy charged for. Thus, for every hundred quantities of energy which the consumer has really employed usefully, he pays for 16·96 more, of which 5·26 has been supplied but consumed in the house lines, and 11·70 has not been supplied at all, and the price for which goes into the undertakers' pockets. But there is a third method. The meter in this case measures only the time the supply has lasted. It may be in the form of a watch which, by means, perhaps, of a magnet loosening a catch, goes on while the current is flowing, but quite independently of the strength of the current. In this case the pressure and the current both are to be estimated as if the standard pressure were maintained. They may both be only 9·10ths of these values. In this case for every 100 quantities of energy which the consumer has really employed usefully he pays for 129·95, of which 5·26 has been supplied and consumed in the house service, and 24·69 has not been supplied at all, though the price for it goes to the undertakers. The fourth method of charging will be worse than the third unless the consumer takes the current during more than eighteen hours per day, which is very improbable. Not only is the margin allowed in the estimate of the energy consumed very excessive, but the actual price of the energy is very high. It is true that there is at present but little experience in the question of the cost of such undertakings, but if the uncertainty prevailing on the subject be a reason for allowing a high maximum charge to the consumer it is also a reason for imposing a sliding scale by which that maximum may be lowered upon a certain amount of profits being earned. But there is by no means absolute uncertainty on the subject. Dr. Siemens has estimated that electrical energy can be produced at a cost of less than 1¼d. for each of those units for which the Brush Company propose to charge 8¾d. or 7d. After making every reasonable allowance it is difficult to see how the proposed prices can fail to leave enormous and excessive profit to the undertakers. I therefore recommend that a sliding scale should be introduced by which an 8 per cent. dividend should be made contingent on a supply of energy at 3d. per unit. In Section 39 the undertakers seek to put obstacles in the way of the use of secondary or storage batteries in certain cases. There is nothing in this clause that is at all beneficial to the undertakers, and much that is inconvenient and vexatious to the consumer. I beg to point out that it is not proposed to exclude the use of dynamo machines, but only of storage batteries. Now, the action of these batteries upon the system while they are being charged is precisely the same as that of dynamo machines, the difference to the customer being that in the case of storage batteries he has the power to use the energy given into them when he wishes, whereas in the case of the dynamo machine he must use it at once. Why should he not use the energy supplied to him, and to be paid for by him, in other than the hours of supply? There is no good reason why he should not do so. . . . When it is taken into consideration how extremely useful storage batteries would be in the case of any break down in the supply contemplated by the undertakers themselves as liable to occur, I submit that this section is not only unreasonable but oppressive, and recommend that it be struck out."

ENERGY.

Method of Charge.	Consumed between the poles of consumer.	Consumed between junctions with main.	Charged for.
First method	100	105·26	105·26
Second method	100	105·26	116·96
Third method	100	105·26	129·95

The report favours a continuous supply, and recommends the consumer to "buy" power and not current—that is to pay for "watts," not "amperes," and contends that by so doing he is less likely to be overcharged. We think we have indicated the most important features of this report, and will only add that when "energy meters" are wanted no doubt they will be forthcoming.

THE INSTITUTION OF CIVIL ENGINEERS.

The last of the series of lectures on the Practical Applications of Electricity, being on "Electrical Units of Measurement," by Sir William Thomson, F.R.SS. Lond. and Edin., M.Inst.C.E., was delivered on Thursday evening, the 3rd of May, 1883.

The lecturer began by observing that no real advance could be made in any branch of physical science until practical methods for a numerical reckoning of phenomena were established. The "scale of hardness" for stones and metals used by mineralogists and engineers was alluded to as a mere test in order of merit in respect to a little understood quality, regarding which no scientific principle constituting a foundation for definite measurement had been discovered.

A short historical sketch was given of the development of scientific measurement, as applied to electricity and magnetism, from its beginning with Cavendish, about 100 years ago, to the adoption of the absolute system of measurement by this country in 1869, at the instance of the British Association Committee on Electric Standards. The importance in this development of the originating works of Gauss and Weber was pointed out, as also of the eight years' labours of the British Association Committee. This committee not only fairly launched the absolute system for general use, but also effected arrangements for the supply of standards for resistance coils, in terms of a unit, to be as nearly as possible 109 centimetres per second. This unit afterwards received the name of the ohm, which was adopted from a highly suggestive paper which had been communicated to the British Association in 1861, by Mr. Latimer Clark and Sir Charles Bright, in which some very valuable scientific methods and principles of electric measurement were given, and a system of nomenclature—ohmas, kilohmas, farads, kilofarads, volts and kilovolts—now universally adopted with only unessential modification, was proposed for a complete system of inter-dependent electric units of measurement. At the International Conference for the Determination of Electrical Units, held at Paris in 1882, the absolute system was accepted by France, Germany, and the other European countries, and Clark and Bright's nomenclature was adopted in principle and extended.

Gauss's principle of absolute measurement for magnetism and electricity is merely an extension of the astronomer's method of reckoning mass in terms of what may be called the universal gravitation unit of matter, and the reckoning of force, according to which the unit of force is that force which, acting on unit of mass for unit of time, generates a velocity equal to the unit of velocity. The universal-gravitation unit of mass is such a quantity of matter, that if two quantities, each equal to it, be placed at unit distance apart, the force between them is unity.

Here mass is defined in terms of force and space, and in the preceding definition force was defined in terms of mass, space, and time. Eliminating mass between the two, it will be found that any given force is numerically equal to the fourth power of the velocity with which any mass whatever must revolve round an equal mass, fixed at such a distance from it as to attract it with a force equal to the given force. And, eliminating force between the two primitive definitions of the universal-gravitation system it will be found that any given mass is numerically equal to the square of the velocity with which a free particle must move to revolve round it in a circle of any radius, multiplied by this radius. Thus, take a centimetre as the unit of length, and a mean solar record as the unit of time, and adopt 5·67 grammes per cubic centimetre as the mean density of the earth from Baily's repetition of Cavendish's experiment, and suppose the length of the seconds' pendulum to be 100 centimetres, and neglect the oblateness of the earth and the centrifugal force of its rotation (being at the equator only $\frac{1}{289}$ of gravity) the result for the universal-gravitation units of mass and force is respectively 15·36 French tons, and 15·36 dynes, or 15·07 times the terrestrial surface weight of a kilogram.

The ultimate principles of scientific measurement were illustrated by the ideal case of a traveller through the universe who has brought with him on his tour, no weights, no measures, nor watch or chronometer, nor any standrd vibrator or spring balance, but merely Everett's units and constants and a complete memory and understanding of its contents, and who desires to make for himself a metrical system agreeing with that which he left behind him on the earth. To recover his centimetre the readiest and most accurate way is to find how many wave lengths of sodium light there are in the distance from bar to bar of a plating which he can engrave for himself on a piece of glass. How easily this is done, supposing the grating once made, was illustrated by a rapid experiment performed in the course of the lecture, without other apparatus than a little piece of glass with 250 fine parallel lines engraved on it by a diamond, and two candles and a measuring tape of unknown divisions of length (only used to measure the *ratio* of the distance between the candles to the distance of the grating from either). The experiment showed the distance from centre to centre of consecutive bars of the grating to be thirty-two times the wave length of yellow light. This being remembered to be $5{\cdot}89\times10^{-5}$ of a centimetre, it was concluded that the breadth of the space on which the 250 lines are engraved is $250.32.5{\cdot}892.10^{-5}$, or ·4726 of a centimetre. According to the instrument maker it is really ·5 of a centimetre! Five minutes spent on the experiment instead of one, and sodium flames behind fine slits, instead of open candles blowing about in the air, might easily have given the result within one-half per cent. instead of 4½ per cent. Thus the cosmic traveller can easily recover his centimetre and metre measure. To recover his unit of time is less easy. One way is to go through Foucault's experimental determination of the velocity of light.

But, he must not be imagined as electrically-minded; and he will certainly, therefore, think of "v," the number of electrostatic units in the electro-magnetic unit of electricity; but he will, probably, see his way better to doing what he wants by making for himself a Siemens mercury unit (which he can do easily, now that he has his centimetre), and finding (by the British Association method, or Lorenz's with Lord Rayleigh's modification, or both) the velocity which measures its resistance in absolute measure. This velocity, as is known from Lord Rayleigh and Mrs. Sidgwick, is 9,413 kilometres per mean solar record, and thus he finds, in mean solar seconds, the period of the vibrator, or arbitrary-unit chronometer, which he used in his experiments.

Still, even though this method might be chosen as the readiest and most accurate, according to present knowledge of the fundamental data for recovering the mean solar second, the method by "v" is too interesting and too instructive in respect to elimination of properties of matter from our ultimate metrical foundations to be unconsidered. One very simple way of experimentally determining "v" is derivable from an important suggestion of Clark and Bright's Paper, referred to above. Take a Leyden jar, or other condenser of moderate capacity (for example, in electrotastic measure, about 1,000 centimetres), which must be accurately measured. Arrange a mechanism to charge it to an accurately measured potential of moderate amount (for example, in electrostatic measure, about 10 c.g.s.; which is about 3,000 volts), and discharge it through a galvanometer coil at frequent regular intervals (for example, ten times per second). This will give an intermittent current of known average strength (in the example, 10^5 electrostatic c.g.s or about 1/300,000 c.g.s. electro-magnetic, or 1/30,000 of an ampere), which is to be measured in electro-magnetic measure by an ordinary galvanometer. The number found by dividing the electrostratic reckoning of the current, by the experimentally found electro-magnetic reckoning of the same, is "v," in centimetres per the arbitrary unit of time, which the the experimenter in search of the mean solar second has used in his electrostatic and electro-magnetic details. The unit of mass which he has chosen, also arbitrarily, disappears from the resulting ratio. It is to be hoped that before long "v" will be known within 1s. 10d. per cent. At present it is only known that it does not *probably* differ 3 per cent. from $2{\cdot}9\times10^{10}$ centimetres per mean solar second. When it is known with satisfactory accuracy, an experimenter, provided with a centimetre measure, may, anywhere in the universe, rate his experimental chronometer to mean solar seconds by the mere electrostatic and electro-magnetic operations described above, without any reference to the sun or other natural chronometer.

The remainder of the lecture was occupied with an explanation of the application of the absolute system in all branches of electric measurement, and the definition of the now well known practical units founded on it, called ohms, volts, farads, microfarads, amperes, coulombs, watts. The name mho, found by saying ohm to a phonograph and then turning the drum backwards, was suggested for a unit of conductivity, the reciprocal of resistance. The subdivision, millimho, will be exceedingly convenient for the designation of incandescent lamps.

The British Association unit has been found by Lord Rayleigh and Mrs. Sidgwick to be ·9868 of the true ohm (10^9 centimetres per second), which differs by only 1·50 per cent. from ·9870, the number derived from Joule's electro-thermal measurements described in the British Association Committee's report of 1867, with 772 Manchester foot-pounds taken as the dynamical equivalent of the thermal unit from the measurement described in his Royal Society paper of 1849, and confirmed by his fresh measurement of 20 years later, published in his last Royal Society paper on the subject.

It is satisfactory that, whether for interpreting old results, or for making resistance coils anew, electricians may now safely use the British Association unit as ·9868, or the Siemens unit as ·9413, of the ohm defined as 10^9 centimetres per second.

INDEX TO VOL. X.

With our present issue we publish an index to the volume of which it forms the last number, viz., Vol. X. Each number as issued from this office contains this index, consisting of eight pages, and no extra charge is or should be made for it.

LONG DISTANCE TELEPHONY.

The startling advertisement which appeared at portentous length in the newspaper columns one day last week, inviting subscriptions to the Long Distance Telephone Company, will have aroused very conflicting emotions in the breasts of persons interested respectively in existing telegraph and telephone affairs. To both alike the incident must have been somewhat alarming—at all events until the next morning. Local telephony has not yet accomplished long distance telephony to any appreciable extent, nor has it promised to do so. It does not, in fact, include long distances in its programme. Now a long distance telephone company, on the other hand, may be supposed to include short distance telephony from the very outset, and thus presents itself not merely as doing something more than the existing companies do, but all that they are able to do besides. Its prospectus, therefore, is not very cheering news for local telephony.

To the Telegraph Department the announcement of a formidable rival being in the field is perhaps more irritating than alarming. Just when the Chancellor of the Exchequer has been so provokingly zealous as to require them to risk the loss of a quarter of a million or so per annum in reducing their tariff, the officials are confronted with another caterer for public favour, and one which, if a third of its expectations are realised, will swell their losses still more. Those expectations may not be realised—they may not even be allowed to have a chance of being realised; but then there is the trouble, and vexation, and odium attached to preventing them doing so by force of law; and the Government had quite enough of that kind of experience when it fought its battle with the original telephone companies. At the moment of our writing it is by no means certain that this long distance telephonic project will be floated; but if it be floated its capital of £600,000, even after the vendor has received his handsome allotment of £175,000 in shares, will afford ample margin for entering the Courts of Law with a light heart, confident in the assurance of bringing the Government into discredit, and of winning the public over to the side of the enterprising competitor. Such a contingency cannot be contemplated with perfect indifference, we may imagine, even in the dignified precincts of the General Post Office.

From another point of view, however, the Postal Telegraph Department cannot fail to get some sort of comfort out of the appearance of this threatened rivalry. It justifies their action in the matter of the telephone companies, and more than warrants their having asserted the right of the Government to the monopoly which, at the instigation of the public, it acquired for the public benefit. The assertion of that right was by no means too emphatic, considering the public revenue at stake; nor has the exercise of it been in any way, so far as can be discovered, detrimental to public convenience, or to private enterprise. What the department has lost by the introduction of telephony and by its being conducted for profit chiefly by competing companies instead of by the telegraph administration it is impossible to say. One thing, however, is made pretty clear by the prospectus now before us—that the risk would have been greater and the loss more certain if the original meaning of the Telegraph Acts had not been upheld in a court of law. Matters are made simpler by that decision, and probaby safer, though in view of the uncertainty of the law it is impossible to say that they are made quite sure.

The thorough-going denouncers of Government monopoly will, one may be permitted to hope, experience an interval of rational reflection. They can hardly avoid seeing that their arguments have been pushed to their logical and ridiculous conclusions by this Long Distance Telephone Company. If a telephonic message is not a telegram over a distance of two or three miles, it can hardly be said to be a telegram if it annihilates space and time, to quote the words of the prospectus, in bridging a distance which, in common language, is described as two or three hundred miles. There is no essential difference, one would imagine, between a short speaking wire run over a few house tops inside a town, and a long speak-

Digitized by Google

ing wire erected on a thousand poles alongside the railroad. Lastly, there is nothing to choose, from a logical point of view, between a thick wire and a thin one, between copper and iron, or between a patent of one telephone and a patent of another telephone. Yet if the arguments current at the time of the first great telephone suits were sound and good for the case they were then put forward to support, they are sound and good for the purposes of the Long Distance Telephone Company. We should not be greatly surprised if the very people who were foremost in asserting that a telephone was not a telegraph are now the first to discover that a telephone is not a telephone if it speaks beyond the area of an "Exchange."

We have no wish to discount the merits of the inventions, whatever they may be, which have justified the promoters of the new company in starting so formidable a scheme; nor can any reasonable objection be taken to the scheme itself, as such. If we are now able to telephone over long distances as easily as over short distances, by all means let it be done. Even if, as may possibly be the case, the expense be far greater, the public may be willing to incur it for the extra convenience, and there is no harm in their being allowed to do so. If we might take exception to anything in this prospectus, perhaps it would be, firstly, to the absence of explicit statement as to cost, say, of ordinary telegraph wires, compared with that of extraordinary telephone wires; and, secondly, the presence of a quotation from a statement of Mr. Fawcett in the House of Commons, made with reference to a quite different matter, but here reproduced for the obvious purpose of anticipating objections to the new scheme on the score of its clashing with the views of the Department over which Mr. Fawcett is the head. In other respects, the document is candid enough—almost too candid; for it tells us that the promoters intend to erect wires between London and most of the important towns in the kingdom, and that it will put the people of these places in communication with each other at the rate of, say, one shilling for every five minutes' conversation. Sixpenny telegrams will have uphill work to compete with telephone "conversation" at that rate, and we should fancy that if the Postmaster-General were again interrogated on the subject he might not be quite so ready to "favourably entertain" proposals for licenses coming from a quarter so unlooked for and so threatening.

CORRESPONDENCE.

ELECTRIC LIGHTING OF NOTTINGHAM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with very great interest the specification and tender for the electric lighting of the borough of Nottingham which appeared in your last issue. I regard the publication of this tender as an epoch in the history of electrict lighting. Remarks which I have already heard indicate that it has awakened a new interest in the subject. After all we have heard of bubble companies, dividends from the sale of concessions instead of honest work, and cheap installations intended to bring an indirect profit through the medium of the Stock Exchange, a genuine tender from such a company as the Telegraph Construction and Maintenance Company is especially valuable, and will do more than almost anything else to establish public confidence. Every one knows that a tender from such a company is based upon true commercial principles, and calculated to return a fair profit to the contractors, and that if unforeseen difficulties should occur the company would carry out their contract, even if it cost them twice the sum stipulated.

One point which this tender demonstrates very clearly is the fact that the total cost of lighting a large town is much less than has been supposed by some persons, and it proves this in the best possible manner—viz., by bringing forward a responsible company willing to undertake the work at the price named.

Taking the engines, boilers, dynamos, &c., as specified, and assuming everything to be the best of its kind, the capital cost of the installation seems reasonable enough, and I have no reason to doubt that it would pay a fair profit to the company. I agree with you in thinking that the limit of 1,750 amperes per square inch of main is far too high. In an installation of this sort the section of the mains must be determined upon the score of economical working, and not simply from the consideration of not overheating the conductors. In an installation in which the *mean distance* of the lamps from the dynamo is 300 yards, I think the current should certainly not exceed 1,000 amperes per square inch. The fulfilment of this condition will slightly increase the cost of the installation.

I have, however, found a few difficulties in endeavouring to adapt the comparison of the working expenses of the installation with the cost of gas to the case of ordinary non-manufacturing towns, such as those with which I am most familiar. Of course, only those who have a local knowledge of Nottingham, can tell whether the great consumption of gas in the factories or warehouses justifies the figures given in the appendix to the specification. I shall therefore assume that the figures are strictly accurate for the district to which they refer, which is well known to be of a very special character, and simply state my difficulties, in the hope that some of your readers who have a practical knowledge of the working of electric light installations as applied to towns, or more information than I can give respecting gas distribution, will be able to correct my conclusions, and solve my questions. In bringing forward these difficulties I am actuated by the belief that the best thing to favour the development and adoption of the electric light is the full and free discussion of every point connected with it. I believe that it will be the light of the future, and that in many localities it is qualified to be the light of the *present*.

I may notice, in passing, the question of water for the condenser. At the low rate of 5d. per 1,000 gallons, the condensing water required for 6,360 horse-power for 2,500 hours would amount to at least £10,000 per annum. This, of course, means that a cooling pond *must* be employed, though it may be at a distance of a couple of miles, and a separate engine must be used for raising the condensing water.

I propose now to consider a town of 180,000 inhabitants, which is, I think, of the same order of magnitude as Nottingham, but I shall exclude from consideration all large manufacturing establishments. Such establishments are, of course, a great advantage to the electric light undertakers, but the advantages to be derived from them can be readily determined in each town by those having the requisite local knowledge.

The total annual consumption of gas by a town of 180,000 inhabitants, excluding factories, may be taken to be about 900,000,000 cubic feet, or at the rate of about 5,000 cubic feet per head. The gas rental from this at 2s. 6d. amounts to £112,500. Such a town would cover an area which ought to be supplied from about ten separate centres.

The lights may be divided into (I.) street lights, (II.) business lights, (III.) lights employed in public houses, theatres, and similar establishments which are opened regularly after ordinary business hours, (IV.) lights in churches and other places of public assembly used occasionally, and (V.) private lights.

(I). The street lighting is easily disposed of. For 180,000 inhabitants rather more than 3,000 street lamps would be required, using about 50,000,000 cubic feet of gas per annum (allowing Bray's or Suggs's lamps in the main thoroughfares), and the rental would be (for gas alone) £6,250.

(II.) Respecting the relative number of lights in private

Digitized by Google

houses, and in shops, offices, and other business establishments, I have no accurate information, and should be glad if some of your readers could enlighten me. Perhaps we shall not be far out if we assume that 200,000,000 cubic feet are employed in ordinary business establishments. From inquiries made in a large business town during the last few days, it appears that the average number of hours per annum during which the lights in ordinary retail business establishments in a provincial town are burning is about 700. This means that about 56,000 lights would be required for business purposes to attain the above consumption. The electric light undertakers must be prepared to light all these lamps at one time, and the income derivable from them would be £25,000 per annum.

(III.) The number of lights in public houses, theatres, and other establishments which are open till a late hour will probably be something like 12,000, burning 60,000 feet of gas an hour, and running for nearly 2,000 hours per annum on the average. The consumption on this score will, consequently, amount to about 120,000,000 feet per annum, with a gas rental of £15,000, or 25s. per lamp.

(IV.) The consumption in churches, chapels, lecture halls, &c., which are open occasionally, may amount to 12,000,000 cubic feet, with a rental of £1,500. The lighting of these buildings will not require any increase in the plant of the engine house, since when churches and chapels are requiring light the business and domestic consumption is small, while lectures, concerts, &c., generally take place after ordinary business hours, and also entail a diminution of domestic consumption.

(V.) Private or domestic lights. Subtracting from our 900,000,000 cubic feet the amounts required for the purposes above mentioned, we have remaining for domestic consumption 518,000,000, producing a rental of £64,750 per annum. It is not easy to determine how many private lights may possibly be going at one time. In my house there are about 45 lights, the number burning ordinarily from dark till 10:30 p.m. is about 11. From 10:30 till 12, about 4, and after that the consumption is negligible. Occasionally the number of lights burning at once is 20, and two or three times a year it may exceed 30. On these last occasions, however, it may be assumed that a number of persons are present and their own domestic consumption reduced. Taking a large area together, it would be safe to provide for the lighting of only 15 lamps in a house like mine, though 45 might be wired, assuming that when more are burning in one house there will be less in another. If I resided at home all the year, my gas consumption would be about 75,000 cubic feet, or 5,000 feet per light per annum. Though in different districts the actual number of lamps in a house may bear very different ratios to the number used at any one time, we may, I think, conclude that for every 5,000 feet of gas consumed per annum in domestic lighting the undertakers of an electric installation must be prepared to light one lamp, or, for a consumption of 518,000,000 cubic feet of gas they must be prepared to light simultaneously 103,600 lamps. The total number of lamps wired in the town might be from two to three times this number.

Hence we conclude that for a town of 180,000 inhabitants lighted entirely by electricity, the undertakers must be prepared to provide sufficient current for 3,000 + 56,000 + 12,000 + 103,600 = 174,000 lamps. The installation, or series of installations, would, therefore, be of about three times the extent of that proposed for Nottingham, while the return would be £112,500 if the electric light is charged for at the same price as gas, at 2s. 6d. per thousand. Factories, mills, warehouses, and workshops of all descriptions would, of course, tell strongly in favour of the electric light.

Judging from the tender of the Telegraph Construction and Maintenance Company, the capital cost of this installation spread over eight or ten centres would probably be very nearly £1,000,000, which does not differ very widely from the value of a gas undertaking capable of supplying the same area.

From the figures just given it appears that the electric light is not much behind gas for price, even when the latter is sold at the low rate of 2s. 6d. But there are very few towns which are not manufacturing towns in which gas is sold at so low a price. The greatest enemy to the commercial success of an electric light installation is the early closing movement, and the enormous number of lights employed in retail business establishments and burning only for 700 hours in the year.—Yours, &c.,

M. N.

May 9, 1883.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 5th inst., under the head of "The Cost of Electricity," you say that the figures given by the Telegraph Construction and Maintenance Company, in their estimate for the Nottingham electric lighting, show a result which surprises you, but which you, after careful consideration, are unable to modify.

Permit me to say that, as far as my information goes, the said estimate is of far too sanguine a character in respect of the income to be derived from the sale of electricity for lighting purposes. An error exists in the assumption that the whole of the 60,000 lamps which the plant is capable of working at once will be used for 2,500 hours per annum. I respectfully submit that no such result is likely to be obtained.

In view of the laying down of the Birmingham Electric Lighting Plant for the Incandescent Electric Lighting Company, Limited, I have caused a most careful house-to-house inquiry to be made of the number of gas burners in use, and the actual revenue derived from them. In only two or three instances has information been withheld, and the results may, therefore, be relied upon. The inquiry has been made throughout the whole of the "specified streets" in Schedule A of the provisional order, that is, those streets in which the undertakers will be compelled to lay down mains within two years after the passing of their Act. Sixteen thousand four hundred gas burners have been counted in these streets, and the mean earning per annum is 10s. 10d. per burner. The earnings vary from 43s. per burner for such premises as underground restaurants, which require artificial light all the time they are open, to 3s. per burner for banks, professional chambers, and the like. The 16,400 burners are situated in the best streets of the town, and on dark afternoons in winter nearly all of them are for an hour or two burning at the same time.

To substitute electric lamps for such burners it will be necessary to put down a plant capable of working nearly all of the lamps at once, or, at the very least, two thirds of them, whereas the annual earnings cannot be greater than those of the present gas burners, unless consumers will pay a higher lamp rental for electricity than for gas. For my own part I fully believe that they will do so, for, in addition to the personal advantages due to living and working in a pure and cool atmosphere, they will find a direct monetary saving in respect of less frequent redecoration of interiors of premises, and absence of damage to goods in stock, books, &c. But, taking the Telegraph Construction and Maintenance Company's estimate of a charge per burner hour equal to that of gas, it will follow that if the Birmingham data may be applied to Nottingham (and I see no reason to suppose that large towns will differ much from each other in this respect), the estimate will stand thus:—

A plant capable of running 60,000 lamps at once *may* represent a gross number of 90,000 lamps wired.

The revenue from 90,000 lamps at 10s. 10d. per annum each will be £48,750, instead of the £93,750 set down in the company's estimate.

The average price of gas being in Birmingham about 2s. 6d. per 1,000ft., it follows that a mean annual earning of 10s. 10d. represents a user of 866 hours per annum instead of the 2,500 hours assumed by the Telegraph Construction and Maintenance Company.

Of course the consumption of coal, water, &c., for electric lighting will be considerably reduced if 800 hours running be substituted for 2,500 hours, but many of the other expenses will remain unaltered, and the net result will be much less than that of the company's estimate.

In many cases a large supplemental revenue may be looked for from the sale of electricity for motive power purposes, but

Digitized by Google

this advantage will be enjoyed only by those companies which use continuous currents. Vendors of alternating currents will have to depend solely upon lighting business.—Yours, &c.,

HENRY LEA, Consulting Engineer.

Birmingham, 7th May, 1883.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In response to your request I venture to submit a few considerations indicating the fallacies which underlie the statement of revenue and profits in the very interesting proposal for a large installation at Nottingham.

As no area is given, nor have I the space marked out on "the map of the district," it is impossible definitely to challenge the particulars leading to a supposed annual revenue of £93,750. We may, however, for the purpose of comparison, compare the area or parish with such a one as St. Martin's-in-the-Fields, in London, which, bounded by the river, extends north as far as Coventry-street, and, commencing at Parliament-street, ends at White Hart-street, Covent Garden. It embraces, therefore, *inter alia*, Whitehall, St. James's Park, Charing-cross, the Haymarket, and nearly all the Strand.

Now, the Nottingham district is to have "60,000 lamps," with an annual revenue of £93,750, whilst an important parish like St. Martin's *possesses only* 980 public lamps, and its gas bill is under £3,000 a year!

But it will be urged that "60,000 lamps" is intended for all private and public purposes within the district. Are we, then, to suppose that gas is to be suppressed, and manufacturers, millowners, and all private persons in the district compelled to exchange it for electric light? Certainly not, for the calculations of "2,500 hours from *sunset* to sunrise" clearly indicates that it is *public lighting alone* that is really contemplated. Again, by calculation it is found that if gas is lit at sunset, and extinguished at 11 p.m., a period of 1,805 hours is reached. So that the 60,000 cannot be intended for private lighting; for, as no one lights up at sunset, or would pay for his illumination "from sunset to sunrise," it is clear that, instead of 2,500 hours' consumption, the very outside would be 1,500 or 1,600 hours.

Allow, however, in the Nottingham district, 1,000 lamps for public use, burning from sunset to sunrise, and we have 59,000 left to be placed so as to average 1,500 hours each, a quantity of gas jets, I do not hesitate to say, that does not already burn in the Nottingham district continuously for 1,500 hours each. Now, no one conversant with existing gas illumination will agree that each jet burns "five cubic feet per hour, giving 12 or 14 candle-power." The plugging up of the pipes and nipples with dirt and chemical constituents soon renders any such theoretical calculation incompatible with what is found in real practice. Yet this is the assumption upon which "60,000 lamps of 20 candle-power" are to be paid for, giving a revenue of £93,750. In other words, we are to compare gas works having a capital of £9,375,000, and paying 10 per cent. thereon, capable of manufacturing and selling 750,000,000 cubic feet of gas at 2s. 6d. per 1,000, with works giving a vastly higher power in photometric value, but only having a capital of £220,000.

The calculations, therefore, to my mind as to revenue are absolutely preposterous, especially when I recollect that in the district in New York to be lighted by Edison, which is one mile square in the busiest part of the city, only the supply of 25,000 lamps is contemplated. The simple way to test the matter is that the public should be supplied with answers to the following questions:—

1st. What number of lamps are now employed in public lighting in the district at Nottingham?

2nd. What is the lineal extent of the mains and connections to be laid down?

3rd. What is the sum now paid privately for gas in the district?

As managing director of an electric light company, it will not be supposed that I am on the "gas side;" but as extravagant or misleading calculations, quite unintended, I feel sure, in the Nottingham undertaking case, only retard the "good time coming" when all shall take to electricity, I am desirous of bringing such to the sober grindstone of truth.—Yours, &c.,

EDW. H. WINFIELD.

THE SOCIETY OF TELEGRAPH ENGINEERS.—THE MICROPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I observe from your report of the last meeting of this society that I have caused your reporter to understand me to say that metal microphones were not "reversible," and did not act as receivers. On the contrary, I exhibited a metal microphone receiver which I had specially made to demonstrate that metal microphones are reversible as well as carbon ones, and that the reversibility is due to some general property of microphonic action, and not to any special property of carbon.

This property is, it appears to me, a repulsion which can be proved to exist between the microphone points when the "discharge" is going on between, and it acts, as I have elsewhere pointed out, like a reacting spring between the vibrating points.

The metal microphone receiver consisted of a pile of wire gauze squares in circuit with the line, and confined between a mica tympan and an electrode. The passage of the current through them set the tympan into audible vibration.

The metal microphone transmitter patented by Mr. Theiler is a simple hammer and anvil microphone of the kind employed before by Professor Hughes. Metal microphones of this kind are, I fear, not quite practical, owing to the "stiction," mentioned by Mr. Bidwell, and to wasting of the points.—Yours, &c.,

J. MUNRO.

2, Somerset-villas, West Croydon,
May 8, 1883.

THE YOUNGER DAYS OF GAS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following passage in reference to Winsor's Grand National Light and Heat Company is taken from *The Satirist* of 1808, Vol. I., p. 236. It was written, as you see, a long time ago, in the days when gas was young; but if for gas we read electricity it will serve very well to-day to express the hopes and aspirations of those of our brethren who are concerned in electric lighting and the transmission of power:

"Only think! light and heat to be conveyed, like water, through every street in London; and, they do say, that the liquid flame will be conducted, by means of submarine pipes, all the way from Pall Mall to the East and West Indies! supplying in its progress various light-houses, sea-lanthorns, &c., to be erected in divers parts of the Atlantic, Ethiopic, and Indian Oceans, which must prove of infinite service to our shipping in dark nights, and will enable our fleets to detect the enemy's squadrons, should they attempt to steal out of port after sunset. I am likewise assured that it will totally ruin the whole medical profession (another great national benefit) by superseding the necessity of physic, the gas being a sovereign remedy for asthmas, consumptions, and almost every other complaint."—Yours, &c.,

May 8, 1883. J. J. FAHIE.

THE VIENNA EXHIBITION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of April 28, on the above subject you have been misinformed. Will you kindly take a convenient opportunity for stating that telephonic apparatus will not be exhibited by J. Coxeter and Son, but by—Yours, &c.

COXETER and NEHMER.

23 and 24, Grafton-street East, London, May 8, 1883.

ELECTRICAL MACHINES AND THE TRANSMISSION OF POWER.—We have received a long letter from M. Bandsept on this subject, replying to Mr. Gisbert Kapp's strictures on his previous letter to us. We regret that we cannot find room for it in our present issue, and are thus compelled to defer its publication to our next number.

THE INSULITE SEALED BATTERY.

We herewith illustrate a battery which promises to be very useful. Ordinary batteries have certain disadvantages, which in this are overcome, such as loss of liquid by evaporation, which necessitates frequent supervision; the giving off of noxious fumes; fragility, and so on. An attempt has been

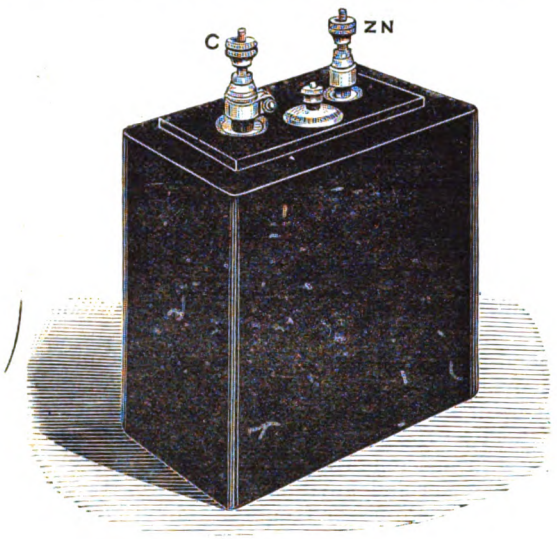

Fig. 1.—Insulite battery.

made to minimise these serious disadvantages in constructing this battery. It is made with an insulite case (Fig. 1), having a carefully and specially-prepared diaphragm, D, placed diagonally across, as shown in Fig. 2. The materials used in charging the cell are somewhat a modification of those in an ordinary Leclanché, viz., carbon surrounded by small lumps of carbon, and zinc, with a special excitant, harmless, non-corrosive, and non-poisonous. No gas is given off. An insulite lid is fitted upon the cell, and autogenously soldered on. Three holes are

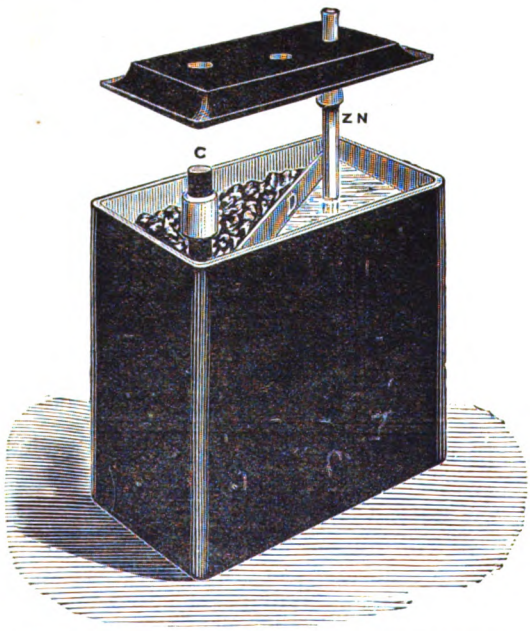

Fig. 2.—Insulite battery, showing internal arrangements.

left in the lid; through two of these the upper parts of the + and − elements pass, while the third communicates with a stopper and release valve. This valve is provided to allow for the slight variations of pressure in the contained air. The upper parts of the elements are fitted with small rubber cylinders, which by their expansion keep the holes in the lid both gas and liquid tight (see Fig. 2.) The terminals are split cylinders, nickel plated, gripping tightly the elements, which project some ½in. through the lid, and make good contact. The E.M.F. of the cells is said to be about 1·6 volt, with internal resistance of 1·5 ohm. They are made up singly, in couples, or in sets of three, contained in neat and elegant tin cases. With the release valve screwed tight the cells can be placed in any position, which conduces to their portability. It seems to us that the cells as supplied by the Insulite Company will meet a great want. They are sent out ready for use—no skilled labour is required to install them. The most ignorant of country bellhangers could hardly make a mistake in connecting the bells. On board ship they will be invaluable, as there is no evaporation, no slopping, no corrosion, and no attention required. A zinc rod is said to last about two years, and is then easily replaced. As the applications of electricity extend, and the testing of lightning rods, of electric light wires, as well as of telephone and telegraph wires, become ordinary work, a portable battery of this kind will be found very useful. Fig. 3 shows an insulite battery, with bell, bell-push, and wire attached for use in a sick room or elsewhere. The electro-magnets and hammer are all contained inside the dome of the bell, which is itself attached to an insulite block, and firmly held to the battery by the

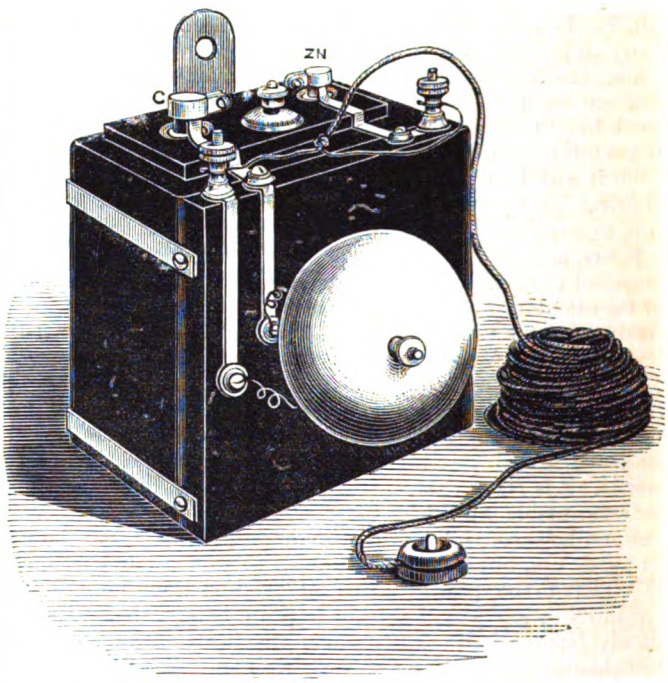

Fig. 3.—Insulite battery, with bell and wire attached.

strips of metal shown in the figure. The connections are so clearly illustrated as to speak for themselves.

MAGNETISM.

BY JOHN T. SPRAGUE.

(CONCLUDED FROM PAGE 595.)

30. The *magnetic field*, consisting of lines of force having *direction* and *intensity*, of necessity varies in force at its different parts; the *unit field* is that which exerts unit force on a magnetic pole; but, as in the mutual reaction of two poles, section 31, this magnet itself is a factor in the force, and $F = m \times H$, where m is the magnet and H the intensity of the field; distance does not enter into the formula because it is already one of the elements which define the intensity. H, which is always used as the symbol of magnetic intensity, is the field produced by the unit pole (Weber) at the distance of one centimetre, and more generally it is as $M \div D^2$, as the strength of the pole and inversely as the square of the distance. It is proposed to call the unit field intensity a Gauss.

31. The *strength of a pole* resembles the unit quantity of electricity, and a unit pole means *one which at one centimetre distance repels an equal similar pole with a force of one dyne*. It is related to the same formula as governs electric force, and $F = \frac{m \times m'}{D^2}$. In fact it is also called the unit of magnetic quantity, and it is proposed to call *it the weber*, a name

Digitized by Google

which, highly proper in itself, will lead to great confusion, because it has been, until recently, the name of unit dynamic electric quantity and current. Its value is 10^8 C.-G.-S. units.

It should be understood that the pole of a magnet *is not a fixed point* in it; it is simply the focus on which the molecular forces combine; therefore this pole or focus will be changed in position by any cause which modifies the field of the magnet, such as the approach of a magnetic substance or another magnet.

32. *Magnetic Moment.*—In mechanics the "moment" of a force is its value under given circumstances, as of the force applied to a lever to move it around its fulcrum. A magnet is a lever, its centre the fulcrum, its poles the point at which the force is applied, and therefore the length of leverage. In such cases the action in opposite directions on the two ends of the lever, exerting an effort, not to move it in any direction bodily, but to turn it on its axis, is called a "couple," and the couple tending to turn any magnet placed at right angles to the pull of the field is $m\,l \times H$, where $m\,l$ is the *magnetic moment*, depending on m the strength of the pole, and l the length or distance between the poles. As a consequence of this, and also of the definition of magnetic intensity, if we have two bar magnets of equal dimensions and equal force, we double the "moment" of one by adding the other to it either end to end, as this gives $2\,l\,m$, or by placing them side by side, which gives $2\,m\,l$. In fact the *magnetic moment of any uniformly magnetised substance is proportional to its volume.*

The moments of magnets may be compared by their relative actions as regards another magnet. If we use the earth as this magnet (and do not need the high accuracy which would take into account the varying magnetic intensity of the earth itself) the moment of a bar magnet may be measured by suspending it by a fibre and counting the time of one oscillation or the number of oscillations in a given time, the relative moments are as the square of the number of oscillations, or inversely as the square of the time of one oscillation.

To obtain the moment in absolute measure a very short needle is freely suspended, so as to hang in the magnetic meridian over a zero line. The magnet is placed parallel to this line, at right angles to and in the plane of the needle, at such a distance that it produces a deflection of only a few degrees. Let θ be the angle of deflection, d the distance between the centres of the needles, H the horizontal component of the earth's magnetism, section 29, then $m\,l = H\,d^3 \tan\theta$.

Horseshoe magnets may be similarly measured if their ends are placed on the line which a bar would occupy, and the distance measured from the central point between them.

Among the examples quoted by Professor Everett, it is said that Gauss found the magnetic moment of a steel bar magnet weighing 1lb. (453·6 grammes) to be 10088 C-G-S. units, and that Kolrausch finds that the maximum permanent magnetisation retained by steel in very thin rods is such as to represent a capacity of nearly five times this. This gives according to these observers :—

Gauss, moment per gramme, 22·24. Intensity, 175 C.-G.-S.
Kolrausch ,, ,, 100·00 ,, 785 ,,

The magnetic moment of the earth is $·33092 \times R^3$ and the earth's radius R being $6·37 \times 10^8$ centimetres, this is 855×10^{23} C.-G.-S. units.

33. The *intensity of a magnet* may be considered as the relation of the force to the mass of matter it is charged on, and therefore varies as the ratio of the magnetic moment to the weight or volume of the magnet; thus, if one bar has a moment equal to that of another of double its weight, it is itself magnetised to twice the intensity. The C.-G.-S. unit of intensity is that of *a cubic centimetre having unit magnetic moment.* The earth's magnetic intensity is only ·0790 which is about ·0004555 of that of Gauss's pound magnet, section 32, and therefore 1 volume of highly magnetised steel has a capacity equal to 2,200 volumes of the earth's mass regarded as a uniformly magnetised body.

34. *Magnetic capacity* would be a suitable name for the maximum intensity which could be imparted to unit volume of any substance. Professor Rowland gives the value in C.-G.-S. units :—

Iron and steel at 12° C.	= 1390;	at 220° C.	1360.
Nickel	,, 494;	,,	380.
Cobalt	,, 800?		

But this is a subject requiring examination, because it is very certain that different qualities of iron and steel possess very different capacities as to *reception* of the magnetism imparted by a given or maximum current, and as to the permanent magnetic force it can retain, section 35. Different authorities give values ranging from 400 to 1000 for steel.

35. *Saturation* implies that a magnet is charged to the utmost the capacity of its materials will admit. Under the influence of an electric current, the magnetism will at first grow in the ratio of the current, but after a time the growth of the current produces a diminishing growth of magnetism, till at length a limit is reached at which no additional current will increase the magnetism. Steel reaches this point sooner than soft iron. But when the magnetising force is suspended, the magnetism is lost to some extent, till an intensity is reached which is tolerably permanent. Iron loses the magnetism almost entirely, though a small "residual magnetism" is always retained. The softer and purer the iron the more freely it absorbs and the more completely it gives up the force.

36. *Coercive force* is a name given to this property of resisting and retaining magnetism. If steel were the only substance possessing it we might attribute it to some insulating or polar action due to the carbon; but as nickel and cobalt both possess it as pure metals, all we can say is that we do not know what imparts the quality.

37. *Consequent poles* are similar poles opposed in the bar of metal as (N——SS——N) where we have the apparent anomaly of a magnet with two north poles: such magnets have uses and are largely used in dynamo machines; but consequent poles destroy the value of ordinary magnets. If a piece of soft iron is applied to the N end of a bar magnet, it is attracted because polarity is induced in it; it becomes itself a magnet with its S end in contact with the magnet. If, now, a second bar magnet is applied with its S end to the other end of the iron, the action is increased, the iron held with double force; but if the N end of this second bar be applied, the two actions neutralise each other, and the iron, though in contact with two magnets, will have only a slight attraction exerted upon it. In this case the armature has consequent poles formed in it and the opposing fields neutralise each other. The same effect is produced if a N pole approaches the end of a piece of iron hanging from a N pole; the iron may fall off. If a S pole were approached, instead of weakening the attraction of the magnet and tending to draw away the iron, the attractive force would be increased.

38. *Auroras.*—These are closely connected with the earth's magnetism, although the exact relation is not known. They are not unfrequently attributed to *electric* discharges, similar to those effected in vacuum tubes, occurring in the upper strata of the air. But the aurora is a general, not a local phenomenon, though it may be more strongly displayed at particular parts. There is ample evidence that auroras are manifested in both north and south polar regions at the same time, while we have no reason to suppose that these have opposite electric charges or conditions, and have very much evidence that electric currents circulate around the earth much as though the earth were an electro-magnet; the reverse action is, however, possible, and the currents might be due to changes in the magnetism. It seems more probable that the aurora is really an illumination of the lines of magnetic force; at all events, the auroral corona always forms around the position of the magnetic pole, and its lines correspond to those of the magnetic field; there appears also to be some connection between the aurora and *parhelia* or mock suns, which are due to a peculiar arrangement of ice particles in the upper air; this renders it probable that the play of light and colour and the shifting streamers of the aurora are due to the magnetic lines of force affecting the constantly varying strata of moisture floating in the air.

Professor Lendstrœm, of Helsingfors, has, it is said, recently produced natural auroras by artificial means. He raised a number of points on the summit of two hills, one of them 3,600ft. high, in 67° N. lat., connecting these points to earth at the foot of the hill; an aurora was formed rising 300ft. in the air, and exhibiting the true auroral spectrum. This result, due to development of lines of atmospheric electric discharge, is probable, because the aurora does strongly resemble some forms of electric discharge; but this would not diminish the probability that the natural aurora is a luminous effect of magnetism rather than of true electric discharge.

39. *Magnetic Storms.*—These are the constant accompaniments of the aurora, but often occur when there is no visible aurora. They have been observed to accompany changes in the sun, sudden outbursts of the hydrogen prominences and development of sun-spots. No doubt they influence health and weather, but they have no necessary or obvious relation to these. They consist in the development of strong but fluctuating currents in the earth, which frequently rise to a force of 200 Daniell cells and occasionally to 2,000. The direction is usually from east to west, as though the positive current followed the sun. Telegraph lines running east or west become useless, except by connecting two together to form a complete circuit independent of the earth; but lines running north and south are comparatively unaffected.

On 17th and 18th November, 1882, a severe magnetic storm affected the whole earth, and suspended telegraphic communication in great degree. It was accompanied with a brilliant aurora. There were also heavy snowstorms in many places, and at the

Digitized by Google

same period there were several large sun-spots forming in the sun. Paragraphs went the round of the papers saying that "by means of the storm alone, electric lights requiring eight horse-power were kept burning some time." This, however, resolved itself into the fact that an eight-candle Edison lamp had been illuminated. During this storm the earth's magnetism underwent rapid fluctuations, and the declination varied 1° 18′, and the dip half a degree. Simultaneous changes were observed in Europe, America, and Japan.

40. *Diamagnetism.*—By means of electrical currents and helices, magnetic effects can be developed in all substances, and Faraday and others, by means of very powerful magnets, have proved that magnetic actions do thus occur, modified by the nature of the substances and their molecular arrangement, which lead to a classification of substances as magnetic and diamagnetic.

The first class, when interposed between the poles of a magnet, place themselves with their longer axis in the line joining the poles; the latter arrange themselves across that line. There has been a tendency among some philosophers to attribute this to a force distinct from magnetism, but there seems no sufficient reason for it, as the properties of the magnetic field will explain the facts; it would seem more probable that the diamagnetic substances are those in which the faculty of assuming the magnetic condition is feebler than in air, and that therefore the molecules of air form the field more readily than those of, say, bismuth, and consequently move these latter into the position in which they take up the least portion of the lines of force; thus a tube containing a weak iron solution will be magnetic in air, but suspended in a vessel containing a stronger solution of iron it acts as a diamagnetic substance.

41. Before leaving the subject of magnetism, it will be well to point out the error of the common conception of magnets as inexhaustible sources of force. It is this misconception which has led so many to waste their time in trying to devise perpetual motion machines, of which magnetism was to supply the motive power. It has also given rise to many questions as to how it is that a magnet can impart force to any number of other magnets without itself parting with any force.

Magnets, like springs, can only exert the power which has been put into them; *they have no force of their own.* In the act of magnetising, whether by magnets or by electricity, a certain amount of energy is charged upon the molecules just as it would if each of the molecules in Fig. 4 were a spring which was wound up in the act of magnetising. When the magnet exerts any force, *it parts with that force;* it is to that extent exhausted, and the energy it parts with is distributed over the new "field," or in the armature, &c., which has been moved. If the armature is a mass of iron as large and heavy as the magnet can hold, the magnet is exhausted; it will no longer affect external magnets, &c., or but very slightly. Before the magnet can exert any further force the requisite energy must be restored to its molecules. This is done by removing the armature, which requires an exertion of force equal to that exerted by the magnet in attracting it.

The distinction is simple, but important; the common idea regards the removal of the armature as an exertion of force against the power of the magnet, and in some sense this is so. But the real action is the restoring to the magnet the force which it has given up to its armature, which is effected by the molecules themselves so long as they retain the magnetic condition.

So in the act of magnetising, it is not the magnet which gives the force, but the energy expended in the act, just as in cutting a piece of iron with a steel chisel it is not a force in the chisel which does the work. The magnet and the chisel have each certain molecular properties which enable external energy to produce the desired effect; in the one case of effecting a molecular arrangement in the steel bar; in the other of destroying the molecular arrangement and cohesion of a piece of iron.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY (LIMITED).

The nineteenth half-yearly general meeting of this Company was held at the Cannon-street Hotel on the 4th of May, 1883, under the presidency of the vice-chairman, Sir James Anderson.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting, and the minutes of the last general meeting, which were confirmed by the present meeting. The report of the directors, an abstract of which has appeared in *The Electrician*, was taken as read.

The CHAIRMAN said he was sure the shareholders would join with the directors and himself in regretting the absence, through illness, of the noble chairman of the Company (Viscount Monck). Everything concerning the Company was going on well, and there was very little to draw their attention to in the accounts. The increase in the receipts over the corresponding six months of the previous year had been £1,700. There had been an increase in the London expenses of £230, but at the stations they had shown a decrease of £23. The increase in the London expenses was owing to their having had to paint their office, and to renew their furniture. He was happy to say that their reserve fund now amounted to about £360,000. He admitted that this was a meagre statement to make to them, but there was really nothing to say to them with respect to the half-yearly report before them. Probably, however, some of them would know that the Company was now face to face with an opposition line which had been laid down along the West Coast of South America. They were not yet suffering from this opposition, though the other company was taking traffic at lower rates, but no doubt they would have to face a reduction of tariff before long. Still, his own idea was that the increase in the traffic would in a short time recoup the loss of revenue, as they had a very high tariff—the highest tariff, he believed, of any company in the world. They had had their monopoly for ten years, during which they had developed a trade gradually, and they found that they had always had a growing trade, which, too, was capable of much greater development. They had formed a good reserve fund, and they had also duplicated one of their sections. Some objection had been made by one shareholder to their carrying the interest of the reserve fund to that fund. The Company's solicitor, however, on the matter being referred to him, had informed them that it was quite within their power to do so, and that they ought to do so; and that it was customary among all the cable companies to do so. The policy of this board—and it had been the same at all other cable boards with which he was associated—had been to build up the reserve fund—to, above all things, have the property intact, or to have that at the bank which would enable them to be in that position. That policy had been acted on from the beginning of the Company by the directors, and they had been supported by the shareholders uniformly in adding substantial additions to the reserve fund. It had always been their purpose to add the interest of the reserve money to the reserve fund, as well as the £50,000 a year, which the shareholders sanctioned some few years ago. He did not think that any one who valued the property and knew anything about the risks of submarine cable property laid in very deep water would object to their keeping up the reserve fund so long as a fair dividend was paid. He then moved the adoption of the report and accounts.

Mr. FREDERICK YOULE briefly expressed his pleasure in seconding the resolution.

Mr. LAW inquired whether it had been necessary to take money from the reserve fund to pay for the duplication of the cable, and if any security which had been sold had realised a profit.

The CHAIRMAN replied that they had sold none of the securities. They had managed with current money, and by borrowing a small sum, to do the work. They hoped they would go on in the same way, and duplicate the whole of their cable. The cost had been charged to the reserve fund. He then put the motion, which was carried unanimously.

Mr. LAW thought the directors deserved very great credit for the way in which they had conducted the affairs of the Company, and therefore moved a vote of thanks to them.

Mr. CRANEY seconded the motion, which was carried unanimously.

The CHAIRMAN having acknowledged the vote, the meeting separated.

THE ELECTRIC LIGHTING, CONTRACT, AND MAINTENANCE COMPANY (LIMITED).

The second ordinary general meeting of this Company was held at the Cannon-street Hotel, on the 9th inst., under the presidency of Mr. Martin R. Smith.

The CHAIRMAN reminded them that at the statutory meeting last July it was arranged, with the full consent of the shareholders, that no decision should be come to with respect to the policy of the Company until the expiration of six months, in order that they might see whether the course of events would produce any alteration in their prospects, and whether their affairs, which then looked so unpromising, would improve in the interval. He was sorry to say that that had not been the case. They proposed now that the Company should be liquidated. They had, in fact, to confess a failure, and he would inform them of the reasons which had led them to suggest the liquidation of their affairs as being the best course they could adopt. Before doing so, however, he should like to congratulate them on the position of the Company, for which the directors took some little credit. With the exception of a very small sum—liabilities for rent and salaries—their capital was practically intact. They were connected with no system of lighting or the purchase of any patents, and they were absolutely free and independent. The plain truth of the matter was that they had done no business. They had found that it was impossible to procure for themselves to their own satisfaction a proof of profit in any way commensurate with the risks they would have had to undertake. When he said that they had done no business he did not wish them to understand that they had no opportunities of doing business. They had, in fact, had numerous opportunities. They had had proposals and solicitations which would have absorbed their paid-up capital over and over again, but they had all presented considerable risk and small profit. As to the original formation of the Company in March, 1882, when they were established, the electric light was considerably embarrassed for want of capital. Plenty of business of a sort was then offering, the business mainly consisting of offers to take the light on trial at the risk of the patentees supplying it. Great ignorance then prevailed as to the cost of the electric light. The most sanguine expectations were held, and the cost of electric lighting was boldly announced to be considerably below that of gas. If a half, or even a quarter, of that which was then so publicly announced had been borne out by subsequent facts the Company would now be in a different position. The result of this was the electric light mania of last year. They might all remember that dividends of 10, 20, and even 30 per cent. were boldly pronounced possible. Every day fresh systems were started, and new companies were brought

Digitized by Google

out. The first cloud appeared on the horizon in the action of the Legislature with respect to the electric light. There was no doubt that the Legislature were perfectly right in trying, as regarded the new light, to avoid the dangers which they had fallen into with respect to gas. They determined not to fall into the same trap twice, and a Bill was brought into Parliament hampering the electric light most seriously. It imposed the most vexatious restrictions and regulations. One of them was that, if the light was successful and proved to the satisfaction of the authorities, they had the option of taking it over at the expiration of 14 years—he believed the period had been since extended to 20 years. If the light was a success the authorities could take it over, but if it were unsuccessful the company were to bear the loss. Had such legislation been laid down as to gas, he believed they would still have been using oil. The Bill passed last year had done more than anything else to prevent the electric light from competing with gas. The result of all the companies starting was excessive competition. He knew of one instance where the electric light was supplied free of cost, and he knew several other instances where it was supplied at a price which could not possibly pay. The universal offer was the electric light at a price equal to that charged for gas. He did not say that the public were to blame if they took the companies at their word. He knew that consumers fairly laughed at them if they attempted to suggest any excess in the price of the electric light over that charged for gas. He maintained that the electric light could not be supplied at the same price as gas—at least he said that no system, at any rate of incandescent lighting, with which they were acquainted at the present moment could show that it was working at a profit commensurate with the risk they were asked to run. He must say that on the previous day he had been informed that an electric lighting company had made up their accounts, and had realised a profit. He was very glad to hear it, and perhaps knowing that, he ought not to speak so sweepingly; but he would say that, acting on the lines of their prospectus, they had not seen their way to compete with gas. He could quite conceive that a well-managed company, with its own works, manufacturing its own plant, not overburdened with money expended on the purchase of patents, might pay their way, and keep going; but more than that he would not allow. Of course they would understand these remarks only referred to the present. He supposed he was not far wrong when he said that the whole scientific mind of the world was pretty well concentrated on the subject of the electric light, and undoubtedly events moved fast, and a thing that to-day was commercially and scientifically impossible, might to-morrow or next month be an accomplished fact; but they had to deal with matters as they now stood. As they stood at that moment the directors did not see how they could employ the money of the shareholders in electric lighting with any prospect of returning to them a good dividend commensurate with the risks they must inevitably run. He would not go into figures, but he did not think it would be difficult to prove to them that any diminution of the present cost of installation was not very probable, as only two-fifths of the expenditure on installations could be materially affected by scientific discoveries. He had also to call to their mind the very low price of gas in this country. That put the electric light companies at a tremendous disadvantage. He could understand that the electric light could be produced at a very considerable profit at New York and on the Continent, where gas was two or three times the price charged in this country. They must remember that gas companies would not be idle, and that the moment they felt themselves seriously pressed by the electric light companies a great reduction in the cost of gas and great improvements in it would inevitably be seen. He thought they had a proof of that in the improved street lighting which they now saw. Until science had discovered a means of producing the electric light at a price at which it could compete with gas, he for one must say that electric lighting was somewhat hazardous. Science, it was true, might at any moment solve these difficulties. But what they had now to consider was whether, in the absence of any immediate prospect of remunerative business, the directors would be justified in asking the shareholders to postpone the liquidation of the Company? He then referred to the statement of receipts and disbursements, and warmly eulogised the services which Messrs. Lee and Young, the managing directors, had rendered to the Company. It was due to those gentlemen that the Company had not lost any of its capital, and he should propose that they receive 500gs. Of course, the directors were greatly disappointed in having to come before the shareholders with such a story, but they believed in their Company, and had proved their belief by holding about one-fifth of the capital. They still believed in the principles upon which it was founded, and also in the future of electric lighting, but the fact of the matter was they had come into the world a little too soon. Had they begun now instead of fifteen months ago they would have been in a very much more satisfactory position, as he believed that the time was coming when the electric light was going to make a fresh departure. That morning they had received a proposal from a gentleman which he believed was one which would show a very fair return for every farthing of the capital of the Company. The only way by which such a proposal could be fully considered would be by some gentleman proposing the adjournment of the meeting for a month. It came from one of the largest and most respectable companies in the City of London, and he conceived himself that it might lead to very satisfactory business. He concluded by moving the adoption of the statement of receipts and disbursements.

Mr. WHITLEY (shareholder) seconded the motion.

The CHAIRMAN, in reply to a question, stated that he could not mention the terms of the proposal to which he had referred. Having replied to a few other questions, he put the motion, which was carried, as was also the suggestion of the chairman, which was seconded by Mr. Tagart, according 500 guineas to Messrs. Lee and Young.

An extraordinary general meeting was then held, at which

The CHAIRMAN moved, and Mr. YOUNG seconded, a resolution for the voluntary winding up of the Company, the chairman, in reply to a question, stated that the affairs of the Company were in such a position that they would be able to wind up in the shortest time permissible by law. They would be able to return a large portion of the capital immediately.

A vote of thanks to the chairman and directors terminated the proceedings.

GREAT NORTHERN TELEGRAPH COMPANY OF COPENHAGEN.

The annual general meeting of this Company was held at Copenhagen on the 28th April, when F. Zahle, Esq., presided.

The chairman, C. F. TIETGEN, Esq., in reporting upon the condition of the company's cables, observed that with regard to those in Europe, the past year had been the most favourable that the Company had experienced. One of the short cables between Finland and the Aland Islands had been interrupted in the month of January, but fortunately the Gulf of Bothnia, which is generally closed at that time of the year, was free from ice, and the Company had, therefore, been able to effect the repairs within eleven days. With this exception, no interruption had occurred, and even the Danish-French cable, which had in former years given much trouble, had not suffered during the year, and the valuable traffic carried by that cable had thus not been disturbed. It had been different with regard to the cables in the far East, where the interruptions from the usual causes, say anchors and fishing, had been numerous. The cable between Wladiwostock and Nagasaki had been interrupted once, for twenty-three days; the Nagasaki-Shanghai cable six times, for thirty days in all; and the cable between Shanghai and Hong Kong eight times, for sixty-two days. These interruptions might almost be called epidemic, as they nearly all occurred in the early part of the year, whilst during the last six months of the year there had not been a single repair to effect. Notwithstanding these interruptions there had been an increase in the traffic receipts, mainly owing to the successful working of the European cables.

The company's European cable steamer, the "H. C. Orsted," had not been idle, as she had been employed in repairing cables for other parties. Thus, she had in the month of May repaired the Direct Spanish Telegraph Company's cable near Bilbao, and in November the Sound cable, belonging to the Dutch Government. Notwithstanding the amount of work there had been for the company's cable steamer in the far East, the "Store Nordiske," she had also been able to undertake outside work, and had repaired the cable in the Tsugar Strait, belonging to the Japanese Government. The receipts derived from this extra work had considerably contributed to diminish the ordinary expenses of the two ships.

It was to be hoped that the proposed measures for the protection of cable property, signed in November last at Paris by delegates from Governments of all parts of the world, would have the desired effect of diminishing the injury which was constantly being done to cables by anchors and fishing operations. It had been adopted in principle that all damage done wilfully, or in consequence of culpable negligence, should be punishable by fine or imprisonment, or both. It was to be regretted that it had been impossible to get inserted into this protection convention a clause with regard to the actual control of the construction and condition of the different fishing apparatus (amongst which was that cable scourge, the trawl, from which the company's Danish-French cable had suffered so much); but, as it was, a good beginning had been made, as a basis for international legislation had been established, which would no doubt be further developed in the future.

But with all this, the best, the safest mode of ensuring regularity in the service of telegraph routes, was undoubtedly duplication. This not only increased speed under ordinary circumstances, but prevented cessation of work during a breakage. The excellent results of this duplication, and he might with regard to some routes say triplication, as introduced in the company's European system, had for some time past had the full attention of the board as regarding the company's lines in the far East, for which it had hitherto been impossible to provide such a reserve. The Company had, however, during the past year succeeded in obtaining the desired conditions for carrying out such duplication in the far East. It being in the interest of the Japanese Government, and also in that of the Russian Government, on account of their land line system, that this duplication should be carried out, the Company had been enabled to make satisfactory arrangements with both Governments. The Japanese Government had given the Company the exclusive right to connect Japan by telegraph cables with the Continent of Asia and the adjacent islands for the next twenty years, which term may subsequently be extended. The Russian Government, following the example of Sweden and Norway, had likewise extended all the concessions of the Company for their connections with the Russian coasts up to the year 1912. These preliminaries having all been arranged, the Company had made a contract with the Telegraph Construction and Maintenance Company, in London, for the making and laying of the cables from Wladiwostock to Nagasaki, and from Nagasaki to Shanghai. The manufacture of the same had now been nearly completed, and the cables were expected to be laid and in working order in August and September this year. With reference to the cable between Shanghai and Hong Kong, the duplication of which was of as great importance to the Company as that of the other sections, the Company had, always with a view to the consent of the Chinese Government, made arrangements with the Eastern Extension Telegraph Company to the effect that the latter should undertake that part of the duplication. That arrangement was based upon the terms of previous agreements existing between the two companies, and the terms were such that this Company would derive the same benefit as if they had themselves undertaken the duplication. In order to meet the expense of the new lines of the Company, the directors being duly authorised, had, on the 1st of March, issued £300,000 five per cent. obligations, redeemable in not exceeding thirty years. The obligations had been offered to the shareholders and the general public by the Private Bank of Copenhagen, and by Messrs. C. J. Hambro and Son, of London, where nearly the whole amount had been placed. It was a satisfactory proof of the growing confidence of the shareholders in the Company's undertakings that the raising of so considerable a loan had in no wise affected the price of the shares, nor was there any reason why that should have been so, as the interest and redemption would only absorb £20,000 per annum, an amount which might fairly be expected to be earned by an increase of traffic consequent upon the duplication. But even if this expectation should not be realised, which was hardly probable, the amount would easily be covered out of the large sums which had hitherto every year been set aside for the reserve fund, which fund would in future, after the establishment of the duplication, not require such large augmentations.

After referring to the different items of the balance sheet, the chairman

Digitized by Google

closed his remarks by assuring the shareholders of the directors' continued confidence in the future of the Company, a confidence they had shown by proposing an increase in the dividend, which would thus be 8 per cent. for the past year. Without discussion, the report was then unanimously adopted, the accounts were passed, and discharge given to the board of directors. The retiring director, C. A. Broberg, Esq., was re-elected. The shareholders' auditors, His Excellency Admiral Bille and A. Berner, Esq., were also re-elected.

THE HAMMOND ELECTRIC LIGHT AND POWER SUPPLY COMPANY (LIMITED).

The second ordinary general meeting of this Company was held at the Cannon-street Hotel, on the 9th instant, under the presidency of Sir C. L. Young, Bart.

Mr. PHILIP A. LATHAM (the secretary) having read the notice convening the meeting,

The CHAIRMAN said that considering that the business in which they were engaged was altogether new, and considering the great difficulties they had had to contend against in the past year - difficulties and anxieties which were inseparable from the starting of an entirely new undertaking —he trusted they would regard the report as not wholly unsatisfactory. They were able to pay a dividend of 5 per cent., to write off £5,000 from the goodwill and concessions account, to place £3,000 to the reserve fund, and to carry forward to next account £1,088. With regard to their losses, or, perhaps, he should say, their failures of profit in the matter of the Lane-Fox license, when the prospectus of the Company was originally issued, care was taken that the licences should clearly understand that the Company had to offer precisely what Mr. Hammond had acquired from the Brush Company, and therefore the language of the prospectus was rigidly limited to the language of the Hammond concessions, but at the same time the Board, or the majority of them, were under the impression that the Company possessed the exclusive use of the Lane-Fox lamp. The question of practical ownership had never arisen. Consequently, when the then secretary drew up a tariff of prices, there did not seem to the Board anything inaccurate in the words "sole concession for the Brush and Lane-Fox patents." Certain parties purchased concessions from the Company, and the transfers of the licenses were made out in due form, copied from the licenses which they held from the Brush Company, and they were submitted to and approved by the solicitor of the Brush Company. Then the sub-companies came out with prospectuses, with which the Hammond Company had nothing to do, and those prospectuses intimated that the sub-companies possessed the sole and exclusive right to the Lane-Fox patents. On the faith of those prospectuses those companies had their capital subscribed. Then came the collapse of the great speculation in electric light shares, and people began to think how to get out of them. A letter then appeared in the public press stating that the Lane-Fox patent was not held exclusively by the Brush Company or its sub-companies, but that the British Company had the same rights to use the lamp under another name. Then this Company's licencees turned on them, and accused them with selling what they did not possess, and threatened actions for the recovery of the money paid to the Company and the damage sustained. The position was this: They took the advice of eminent counsel, and they were advised that, while they had a strong defence to the threatened actions, the far more prudent course for them to take in the interests of the shareholders would be not to enter into protracted and costly litigation with the sub-companies, the ultimate result of which might be the crippling of the Company's resources and the great detriment of their proper business. Therefore, after long and most anxious consideration, they resolved to take the advice of their counsel—repay the money they had received, and look to the Brush Company to recoup them for the loss they had sustained from the reticence of that company on this important point. He wished it to be understood that he was making no personal charge. A suit was pending between the Company and the Brush Company, who were suing this Company for the balance alleged to be owing on a very large order which the Hammond Company gave them, but which they had withheld in the belief that they had an ample set-off against the claim made on them by the Brush Company. Their claim against that company was far heavier than the Brush Company's claim against them. There were two other suits of a similar nature against the Company which they had not compromised in any way. Parties had paid a certain amount to them in order to secure an option, but those parties had brought out no prospectus or proceeded in any way, and the Company felt that in these circumstances they were justified in keeping the money so paid to them. They had had great obstacles to contend with—he did not allude so much to individual prejudices as to that which was always a difficulty to contend with—the man in possession, the gas companies, who had such a tremendous monopoly. He maintained that if electric lighting had done nothing more it had conferred a great public benefit by compelling the gas companies to light the streets better. Spending a great deal of money, however, to induce other people to do their duty was not usually a commercial success, and what they had to do was to go on until they attained that measure of success to which they knew they were entitled, and which they felt sure was not far off. The Electric Lighting Act, which at first seemed prejudicial to them, was really a great step in their favour, for it had given parliamentary recognition to a great fact, and, though only tentative, it legalised a position which before was uncertain. They could not complain of the forms and processes which had to be gone through before they got in such a position as the great gas companies; and it was for them to show that they could serve the public better. It had been said that no public electric light contract had shown a profit to the contractor. He was not prepared to admit the accuracy of the statement, but he should like to know what gas company could show a profit from its street lamps if it had not the privilege of the private lighting. With their new Ferranti, which could run 5,000 lights, they could, he maintained, serve a district better than a gas company, and show a profit on the business. Gas was carefully excluded from all the best drawing and dining rooms in favour of oil lamps, nor was gas found in any room in Pall-mall. Was it to be supposed that these people would not, if it were possible, adopt the incandescent system of electric lighting? To light such a district, however, there were great difficulties, and vestries, committees, and boards of works had to be tackled before they could move an inch. Well, they would all have to be tackled. It was a large stone that they had to start rolling, but once started, they would reap the reward of their patience. Meantime, they must content themselves with such progress as they could make privately. In certain quarters they had met with considerable success, and those who had adopted the electric light in their business were not likely to abandon it. He then referred to the progress of the electric light in America, and remarked that when London had a municipality worthy of its imperial position, the citizens would not be the victims of monopolies, but would be in a position to avail themselves of any improvement which science could give us. He then referred to the position of Mr. Hammond, and stated that it was provided in the Articles of Association that that gentleman should undertake the position of managing director without any salary. It was not, however, contemplated at the time that he should give the Company his exclusive services, whereas, as a matter of fact, he had had to give his whole time, thought, and energies to the affairs of the Company. Such a state of things was unfair to all parties, and the directors, therefore, proposed to make an alteration in Mr. Hammond's agreement with the Company, so as to retain his exclusive services. Mr. Hammond had agreed to devote himself exclusively to the interests of the Company for an annual payment of £1,000, and they thought they would be only properly recognising his services in the past year by giving £500. He concluded by moving the adoption of the report and accounts, and the payment of a dividend of 5 per cent.

The MANAGING DIRECTOR (Mr. Robert Hammond), in seconding the motion, stated that among the shareholders he felt that he was addressing an audience perfectly at one with him as to the ultimate future of the business. Let them go back a year, and see the task which had been set before the Company. There were many who seemed to think that the only purpose for which the Company was started, was to keep as much of its capital as possible at the bankers, to save at every turn, and to incur no expenditure in pushing its business. A year ago what was the position of the electric lighting industry. They had just seen the close of the Crystal Palace exhibition. It had been proved most conclusively that the electric light was going to become an immense factor in the lighting of the future; that, in fact, they were in a new epoch —as new as that which greeted railway men when they started the first railway. Some of the companies, and the Hammond Company in particular, impressed with this conviction, immediately prepared for the work which was in future, and they were determined to arrive at such a position that they should get their fair share of the work. In the past year the Company had had this one object before it—to prepare itself for the immense industry coming on, and had striven to make its name well known and respected in every part of England, and to have its name connected with work which would not shame the electric light industry. They had got around them a set of men who could be perfectly trusted to undertake any work given to them. All over England he was constantly meeting men of leading position who were gaining confidence that when he gave them figures they could trust to them. In August, therefore, when the Board of Trade orders were given out, he believed they would find themselves not only able to do the work, but with such a name established, that they would get a fair proportion of the work. At Leeds the chairman of the gas committee had told him that they were convinced of the advantages of the electric light, that did not injure health or property by sulphuretted hydrogen, that a light which in every way was desirable to make the home the happiest and most comfortable spot in the world was the light they intended to have in Leeds, and they assured him (Mr. Hammond) that though they had £1,000,000 invested in gas, that would not deter them from putting down the electric light system on a large scale. This feeling was endorsed in almost every part of England. Confidence had, however, been shaken by the large amount of bad work which had been done in connection with the electric light, and in the past few weeks he had been confining himself almost exclusively to inspiring confidence. The Hammond Company had made itself ready for what was to come, and it could give the most accurate information as to the electric light and its cost. They started as an offspring of the Brush Company, and they had a certain number of counties allotted to them in the North of England in which to work under the banner of the Brush Company. It would have been expected in the circumstances surrounding this Company that it would have had every assistance and advice from the Brush Company, but that expectation had not been realised, and it was very soon seen to be evident that they could not continue under the banner of the Brush Company. The Crystal Palace exhibition was, to a certain extent, disastrous to the interests of the Brush Company. He believed it laid the basis for a future, but it showed people that the Brush was not the only system, and it had all the more reason to put down its prices, and the business should never have been allowed to pass them. Then the Brush Company did what was almost suicidal in the interests of this Company by declaring a dividend of 100 per cent.—not a return of capital but a dividend of 100 per cent. People informed him when he went round that they would have nothing to do with a company which paid such a dividend. He had found it impossible, in face of such a state of things, to persuade people that the machinery was to be had at the lowest possible prices. The Hammond Company saw at an early stage that the future of electric lighting depended on the incandescent system, and they urged the Brush Company to produce machinery that would run 5,000 or 10,000 lights. They could not, when they endeavoured to get a 500-light machine, obtain it, and they were told to add together three machines—two of 200 and one of 100 lights, which would have made £1,800 for a Brush machine to run simply 500 lights. They saw that, linked with the Brush Company and crippled up in the north of England, their prospect was not a tempting one, and they therefore determined to act independently and to see if they could not obtain machinery of their own and to have the whole field to themselves instead of a few counties. At that time a machine was announced which had been invented and patented by a young fellow named Ferranti, who was working at Messrs. Siemens, who, however, found, to his great disappointment, that in the vital part of the machine, the armature, he had been preceded by so great an authority as Sir Wm. Thomson. A fusion of interests at once took place between Mr. Ferranti and Sir Wm. Thomson, who thus acted most nobly. Then arose the question—where was the capital to come from to set up the works necessary in connection with the machine? Finally, he himself paid a deposit of £5,000, and bound himself personally to find the £60,000 required, on the condition that the Hammond Company should become sole agents of the Ferranti machine to

Digitized by Google

the extent of the English patents. He had been called upon to find £25,000 out of the £60,000, but this responsibility had been shared by one of the largest shareholders in the Company. If the Hammond Company wished to take this stake it could do so. The idea of making a machine to run 5,000 lights was seen to be possible with this machine. He had been to Leeds, and had been delighted to see the progress which was being made by the manufacturers with the machine. When the Ferranti machine ran and produced these 5,000 lights, it would cause an immense sensation throughout the whole electric light world. No great work would be done until the provisional orders were out in August, and they felt that they had the year well in hand. What they had to aim at was a machine which would run 50,000 lights, as the object must be to produce the electric light on as large a scale as gas. They were prepared to put up plant to supply 40,000 lights at 2s. 6d. per 1,000 cubic feet, speaking in gas parlance, and where coals were cheap he calculated that it might be done at 1s. 7d. They had had to do with an incandescent lamp which had caused grievous disappointment, and for £2,878 they had secured Wright and Mackie's patents. They had been negotiating for the purchase of an accumulator, and if one was offered to them fulfilling conditions making it the best in the world they would have it. They had had great legal difficulties to contend with, in connection with which they had had the able assistance of Mr. Ince.

Mr. REYNOLDS referred to the progress of the two sub-companies of the Hammond Company at Eastbourne and Hastings, with which he was connected.

Mr. WOOD supported the action of the Board, and expressed his satisfaction with the dividend of 5 per cent.

The motion was adopted, and the auditors were afterwards reappointed.

Mr. REYNOLDS then suggested that a small committee should be appointed to act with the Board in order, if possible, to bring the suit between the Company and the Brush Company to a satisfactory conclusion without [illegible] before a court of law.

The [illegible] assented to the suggestion. The proceedings terminated in the usual manner.

MAXIM-WESTON ELECTRIC COMPANY (LIMITED).

The adjourned general meeting of this Company was held in the Cannon-street Hotel, London, on the 4th inst., under the presidency of Admiral Sir E. A. Inglefield, C.B., F.R.S.

The CHAIRMAN reminded the meeting that they left off on the former occasion by not passing the accounts, which the directors considered as a vote of want of confidence. They then proceeded to the question of electing the two directors who retired by rotation. The two directors were Mr. John Scarlett Campbell and Mr. Hugh Watt. But it seemed, as the shareholders had not sent in any names of gentlemen to take the places of Messrs. Campbell and Watt, that those gentlemen had been virtually re-elected, or remained directors for another year. That they were advised was the legal state of the case. But to show that, as a Board, they had no desire to remain as managers of the affairs of the Company without the shareholders' confidence, they had passed a Board resolution, by which they desired to offer their resignation. It was necessary that the shareholders should elect another Board, whose names must be sent in seven days beforehand. For that reason it was proposed to dissolve this meeting. In the meantime the interests of the Company would not in any way be neglected, as the present directors retained their seats. They would remain in office and do their best for the Company till other gentlemen had been appointed. The only difficulty would be the question of the raising of the new capital. That was all he had to say. The question of the directors was settled; as they would see, by law, but notwithstanding that, they, *en masse*, gave their resignation to the shareholders. It would be necessary to elect an auditor in place of Mr. Dever, who offered himself for re-election.

Mr. LEE proposed, and Mr. ROSSEN seconded, the re-election of Mr. Dever.

A SHAREHOLDER thought, as the accounts were not yet passed, that the election of the auditor should be left until they were passed. It would be very premature on the part of the shareholders, after objecting to the accounts, to re-elect the gentleman who audited them. He could not help feeling that if the directors were to blame the auditor was also.

The CHAIRMAN did not know that Mr Dever had done differently to what had been done in other companies.

Mr. DEVER said that he should be very unwilling to press his re-election on the shareholders, but it was right of him to say that the accounts were not objected to at the last meeting. He thought the shareholders objected to the management, with which he had had nothing to do. It was owing to the accounts being fairly stated, and the expenditure and assets fairly displayed to them, that an opportunity had been given to them to exercise their judgment as to the management of the Company, with which he repeated he had nothing to do.

The CHAIRMAN said he perfectly agreed with Mr. Dever, that he simply had to look through the accounts. The directors were quite willing to bear all the responsibility as to the correctness of the accounts. He would be glad if they would look into them, so that they might see that the charge which had been brought against the directors of frittering away the money could not be substantiated. He put the motion in the usual way, and declared it carried, with three dissentients; and the remuneration of the auditor was fixed the same as last year—30 guineas.

The CHAIRMAN then asked if the shareholders had any question to put to the Board, and added that, in the meantime, he might show them the gold medal which he had received on behalf of the Company when it was called the Electric Light and Power Generator Company. The medal had been received from the Crystal Palace, whither he had gone and received it from the Duke of Teck, as well as a diploma of honour. Theirs was the only company that received a medal for their whole system of lighting.

Mr. SAMUEL asked whether the directors of the Lancashire Company had all paid up the amount of their shares.

The CHAIRMAN replied that had nothing to do with this Company.

Mr. SAMUEL thought it had a great deal to do with the Company, seeing that it was dependent for the receipt of £10,000 owing to it from the Lancashire Company on the calls being paid on that company's shares.

The CHAIRMAN stated that all the directors had paid except Mr. Dadson, who had been elected a director, but had not taken his seat.

Mr. SAMUEL understood that Mr. Dadson had the call of a great number of shares in consideration of his taking up a certain number of shares in the Lancashire Company.

The CHAIRMAN replied that there was a certain option, but that it had lapsed. It was true that there was money owing to them by the Lancashire Company, and they were taking measures to get it paid. They had no doubt that they would get it, but it was not always easy to get in calls within a month or two. In reply to a further question, he said that Mr. Dadson was elected to a seat on the Board of the Lancashire Company, not this Company.

Mr. J. S. CAMPBELL said he was not a director of the Lancashire Company, but he did not think it was right, at their meetings, to express any opinion as to whether or not the Lancashire Board had acted properly or otherwise.

The CHAIRMAN observed that he had joined the Board of the Lancashire Company very much against his will, but he did so only because he thought it would be to the advantage of the parent Company. He had paid his calls in the Lancashire Company, and had sold many of his shares at a severe loss in order to do so. Replying to a shareholder, he added that with respect to the raising of the new capital the directors would naturally have done their best as large shareholders to obtain it. He then intimated that this closed the business of the ordinary meeting, and they would now proceed to the extraordinary meeting. The last extraordinary meeting was adjourned because the general meeting was adjourned, and it was decided that they could not go into this question of the new capital on account of the Board not having had a vote of confidence. The same reason existed now, and [illegible] should propose the raising of [illegible] ers. He thought they would [illegible] regarding the matter. They [illegible] consider the [illegible] of the new capital if they adjourned to that day fortnight. If that was their opinion he would move "That the Board had, in consequence of the resolution showing want of confidence in the directors, resolved to place their resignations in the hands of the shareholders, and that a special general meeting be called on the 18th May, for the purpose of electing a new Board." That would give time for sending out notices, and probably there would be a proposal for the raising of the new capital. He wished to remind them that any one desiring to propose new directors must, to legally do so, give at least seven days' notice before the meeting.

Mr. LEE inquired who the gentlemen were who were to propose the new scheme at the next meeting for the raising of the capital.

The CHAIRMAN: You, if you have a good one. He added that, unless the shareholders had anything to bring forward with respect to the position of the Company, the meeting would be dissolved, and a new meeting would be called for the 18th of May. Meantime they were not without hope that among some of their friends a scheme would be brought before the shareholders which would place the Company in a very fair position.

A SHAREHOLDER inquired, if the meeting were dissolved, when the accounts would be passed.

The CHAIRMAN said that nothing happened if they did not pass the accounts, except that the directors were not satisfied.

The MANAGING DIRECTOR (Mr. Hugh Watt) read a statement with regard to the expenses, in the course of which it was stated that the gross sum spent the previous year was £22,500, while the total of the net expenditure of the year now under review had been £9,000. Adding the £4,000 which ought to have been included in the previous year's expenses, the saving this year, as compared with the previous year, had been equal to about 60 per cent. Out of the £9,000 about half had been on plant. He assured them that one of the directors, Sir Herbert Sandford, had been most painstaking, and audited every account, however small. The expenditure had been considerably reduced, and the production had been materially increased. Replying to other questions, Mr. Watt added that the £4,000 which ought to have been included in the expenses of the previous year represented accounts which had not come in by the 31st March, 1881, and could not, therefore, have been included in the accounts for the previous year. The parliamentary expenses had been in connection with the Electric Lighting Bill, which had been promoted by this and the other companies. The £976 for legal expenses represented the ordinary expenses for the year. A large amount of it was in connection with patents.

The SOLICITOR said that the amount had been practically in connection with the purchase of some patents, and costs for the sale of their patents to other companies. The expense of the promotion of the Lancashire Company had had nothing to do with the £976.

The CHAIRMAN said that they had done all they could to cut down legal expenses, and never employed solicitors except where it was essential for the interest of the Company that they should do so. They were obliged to tack improvements on to their own patents, which came from America.

The MANAGING DIRECTOR stated that the legal expenses from the 10th of November, when he was appointed executive officer, had been £100.

The CHAIRMAN pointed out that every information with respect to the accounts could be obtained at the offices. They had nothing to conceal.

MR. MANDER ALLENDER, as a member of the late committee, observed that, provided the necessary changes were made in the management of the Company, the shareholders ought, and it would be to their interest, to subscribe the new capital. But, on the other hand, unless certain changes were made he should subscribe nothing, and should do everything he could to prevent any one throwing more money away.

The MANAGING DIRECTOR said that this remark was made at him, and, therefore, he desired to say that a letter had been received ——

The CHAIRMAN (interposing), remarked that the matter Mr. Watt was about to refer to was private, and that it was better that it should not be gone into. It appeared that the legal expenses referred to had been for two years.

Mr. LANDON (the late secretary) said that the legal expenses were from the 3rd June, 1881, to the 31st December, 1882—that was to say, for a year and a half exactly.

Mr. INVERARITY thought that there could be no objection to pass a reso-

Digitized by Google

lution increasing the capital to £500,000, leaving the details to be settled at the next meeting. The resolution, if passed, would be for the next meeting to confirm.

The CHAIRMAN considered it would be better to leave the question of raising fresh capital for the next meeting.

A SHAREHOLDER, however, pointed out that the next meeting could refuse to confirm the resolution.

Mr. INVERARITY, at the request of the meeting, then stated that his scheme for raising the new capital appeared to him to be quite feasible, but it was based on the shareholders assisting. His plan was this—that the capital of the Company be increased nominally to £500,000 by the creation of 327,000 new shares of £1 each; that the directors be authorised to issue at once £50,000 of these new shares to the existing shareholders at the price of 6s. 8d. for the £1 share, such price to be paid half on allotment and half not less than three months subsequently. The price of the shares that day was not 6s. 8d. and consequently a shareholder taking up any number of shares at 6s. 8d. had a right to some compensation. He therefore proposed that each shareholder taking up any portion of the 50,000 shares should have the call for a period of 18 months of an additional allotment of two shares of £1 each for every share taken at the same price of 6s. 8d. Therefore, any one taking up one share now at 6s. 8d. would have the call by his plan of two other shares at the same price, so he would practically get three shares for the price of one. He should propose, however, that no general allotment on these terms should take place unless three-fourths of the whole £50,000 were subscribed for. Suppose a shareholder took 50 shares it would cost him £16 13s. 4d. He would pay half of that on allotment and the second £8 6s. 8d. three months afterwards. Hence, for £16 13s. 4d., he would get fifty shares with the option of calling up within eighteen months 100 shares at the same price. As a matter of fact, if every shareholder took thirty-five shares at 6s. 8d., it would place the Company in a most flourishing position.

The CHAIRMAN stated that it was well that the shareholders should have heard this statement. He desired to assure them of his belief that not only in the public mind, but in the minds of most of the other large electrical companies, this Company possessed the best patents extant: and from the continued applications to them for concessions for electric lighting plant and for installations, he was satisfied that it was growing rapidly in the public mind. He concluded by asking them whether it was their pleasure that the resolution increasing the capital should be passed that day, leaving its confirmation for the next meeting.

Mr. INVERARITY pointed out that that would only authorise the creation of the capital that day.

After some further discussion the printed resolutions in the notice calling the meeting were passed as follows:—

"That the nominal capital of the Company be increased by the addition thereto of 327,500 shares of £1 each beyond the registered capital of £172,500, in 172,500 shares of £1 each, making the total capital £500,000.

"That such 327,500 shares may be allotted at the discretion of the directors, on such terms and at such times as they think fit, and either at a premium or at a discount."

A vote of thanks to the chairman and directors brought the proceedings to a close.

ELECTRIC LIGHTING FOR LEEDS.

Last week we gave a brief note stating that the Leeds Corporation had resolved to adopt the electric light for the Town Hall and certain streets. We now give a *résumé* of the proceedings of the meeting at which the above resolution was adopted, taken from a Leeds paper:—"Alderman Tatham proposed—That the council proceed with the application for, and include in, the draft provisional order for electric lighting the following as the areas to be included in Schedules A and B:—namely, Schedule A—So much of the borough of Leeds as is contained within the following boundaries, namely:—From Great George-street along Oxford-place to Park-lane, thence along Park-lane to East-parade and along East-parade, thence along Bond-street to Park-row, thence along Park-row to Park-lane, thence along Park-lane to Calverley-street, thence along Calverley-street to Great George-street, and thence along Great George-street to the commencement of the boundary in Great George-street. The streets within the aforesaid area along which the undertakers are to lay distributing mains, and the places proposed to be lighted by the undertakers within two years from the commencement of the order are the following:—In Victoria-square, in front of the Town Hall; in Calverley-street, in front of the municipal buildings; within the Town Hall, in Victoria-square; and within the new municipal buildings and the new free public library, forming part thereof. Schedule B—The whole of the municipal borough of Leeds, as the same is constituted under the provisions of the Acts relating to Municipal Corporations, and of the local Acts relating to the borough at the date of the commencement of the order, excepting the area included in Schedule A. Continuing, Mr. Tatham said that the Electric Lighting Act was a very intricate measure, prepared with the idea that not only was the electric light to be the light of the future, but that there would be a quick demand for that light. These views had not yet been realised, although they might be in the future. No company had yet been able to take up the work of lighting large towns with success. The Electric Lighting Committee, in the first instance, did not think it advisable to adopt the compulsory powers of the Act, because they feared they might be called upon to carry out something that would be neither profitable nor beneficial. There was some difference of opinion, however, as to the liability they might have to undertake, and legal opinion was obtained. The committee were given to understand that they were not bound to carry out the lighting of any area if it were found to be unprofitable to do so; but that if they did not do so they would forfeit the powers allowed under the provisional order giving them the exclusive privilege of lighting the town. Although some members of the committee thought it would be better to do without an order altogether, and simply be content with lighting the corporate buildings, others were of opinion that it would be well to take a fair area, and supply that area under the terms of the provisional order. After a long discussion in committee, the prevailing sentiment was that they might safely recommend the council to adopt the area suggested in the resolution he had proposed. The provisional order first of all would give power to light the whole of the borough, but it also required that they should define a particular area, to be called area A, in which the council would be bound to supply electricity within two years. When that was done, those living in other parts of the area might, at the expiration of that period, claim to be supplied with the electric light. From time to time the corporation could add portions of area A to area B under the same conditions of supply, and if persons living within 250 yards of area A thought they were not properly supplied, they could apply for an order to compel the corporation to supply them with the light. The committee were of opinion that if they acquired the powers now recommended, they would be able to protect themselves against injury in respect of future competition."
